When a recognized authority, observing that, “by placing the hand upon the pelvis” of the hip-diseased patient “and making gentle extension upon the limb for a few seconds in the line of the deformity, motion can be made at the joint without causing pain”; when, furthermore, he declares that “motion is as essential in retaining a healthy condition of the structure about a joint as light is essential in retaining a healthy condition of the eye”; I say when, in the face of such statements as these, he deceives himself and his credulous followers into supposing, in the first place, that he is closely approximating the kind of force exerted by his hands by substituting for it a *rigid* bar “reaching from the pelvis to the bottom of the foot,” and provided with a mechanism capable of exerting only *rigid traction*; when, in the second place, he lashes, as it were, the entire lower extremity on the affected side to this rigid shaft by attaching it to the limb at the top and bottom and then slipping “the knee-pad band up or down until it is made to rest opposite the knee, when it is passed around the leg and buckled”; when also, in the face of such practices, he declares in a previous paragraph that he “can see no propriety whatever in restraining the movements of this joint” (the knee); when, I repeat, such conflicting statements and practices as these have been enthusiastically and effectively promulgated for years—the time is ripe for no longer tacitly acceding to the credibility of illogical dogmatisms simply because they may appear to have acquired a prescriptive right to our indulgences.

But let us calmly study the salutary remedial lesson to be derived from our knowledge of the action of exaggerated curves and angles in the human body in averting the mechanical effects of jars. We found, in the first place, that the conduction of jars through the body when at rest was most readily accomplished when the individual was in the

erect posture, standing squarely with equal weight on both feet; or, in the terms of our formula, during the continuance of the maximum degree of linear skeletal directness. In the second place, we found, when the direct linear osseous continuity of the erect figure was broken and decomposed into exaggerated curves and angles, that a very remarkable degree of protection against traumatism was secured, the explanation being that the progress of the vibratory wave was interfered with by the obliquity of impact at the osseous angles and curves. That exaggerated osseous curves and angles lessen bone conductivity does not imply that the maintenance of this attitude, partially squatting, is essential to the safety of the individual, but simply that it is desirable that such an attitude can be assumed when occasion requires. The indication to assume this attitude is derived from the information afforded by our senses.

Hence it will readily be seen that, in hip disease, to make use of a rigid shaft which passes over all the joints of the lower extremity on the affected side, to which the limb is lashed, as is customarily done, would be an insuperable barrier to the utilization, in the face of danger, of a remarkably effective normal method of joint protection. Nature's column, capable of instantaneous angular decomposition, is by this means placed in the perilous attitude of permanent linear continuity. The conditions for the conduction of jars are at their maximum degree of perfection, and it matters little whether or not the site of impact be transferred from the foot to the perineum.

But the greatest triumph of mechanical non-expertness in the treatment of hip disease from the physiological standpoint is that elaborated by the far-reaching genius of Mr. Thomas, of Liverpool. In his efforts to remove his therapeutics as far as possible from physiology, he has probably reached the highest degree of divergence; for not only does he strive to immobilize the hip and knee joints, but also to abolish motion, as far as possible, in the spinal column up to the level of the lower angle of the scapulae.

It would be interesting instruction to examine the illogical and unscientific details of this and other plans of treatment advocated for hip disease, but the scope of this paper forbids more than a suggestion in this direction.

The question which next arises, then, is whether exaggerated curves and angles are the only means Nature has for protecting herself against traumatisms?

(To be continued.)

CHANCER OF THE TONSIL.*

By R. W. TAYLOR, M. D.,
SURGEON TO CHARITY HOSPITAL.

This form of chancre, although not common, is not so rare as was once supposed, and it possesses points of much interest.

First, as to its origin. While it may result from contagion from initial syphilitic lesions about the lips and face, as a consequence of kissing, and also from mediate contagion, as by articles like nursing-bottles, pencils, perhaps

* Read before the New York Academy of Medicine, May 16, 1884.

cigars, etc., it is also frequently caused by depraved and unnatural sexual contact, which of late years has increased to an alarming extent in America. These lesions are interesting, also, in their diagnostic relations; and, further, in the fact that there is little doubt that some cases of the *syphilis d'embée*, or *larvée*, of the French were really instances of tonsillar infection, since nothing is more assured than that acquired syphilis always begins in a chancre.

I will detail the cases observed by myself, and refer in brief to the best-authenticated of those now on record.

In June, 1882, a young woman, twenty-two years old, who had been under my care for some time for *timea trichophytina cruris*, complained of slight sore throat. On examination, I found that there was some redness of the left tonsil, extending to the pillar of the fauces of the same side. It was not hard, nor were the ganglia perceptibly enlarged. I ordered a simple gargle, and awaited events. In a fortnight she returned, and then I found that the tonsil was much reddened, swollen, indurated, and exulcerated. Her tonsils had been the seat of simple hypertrophy, and then the diseased one had become much more prominent than its fellow. The induration was almost cartilaginous. She complained of much pain in swallowing, and there was an abundant mucous secretion. The ganglia of the left side of the neck and those under the jaw were much enlarged and matted together into a diffuse mass. She had not had any ulceration elsewhere, and the inguinal ganglia were not swollen until three weeks later. In due time a papular roseola appeared. She was also much troubled with recurring mucous patches. In this case the redness and swelling were limited to the affected side and confined closely to the tonsil. I learned that she had been guilty of unnatural practices, and had thus become affected in the mouth.

I was asked to see the following case by my friend Dr. McBurney. On examination, I found the left tonsil swollen, indurated, and superficially exulcerated, and covered with a whitish, granular film. The induration was well marked. The ganglia of the same side were much swollen, and many of those under the jaw and over the sterno-cleido-mastoid muscle were matted together. I had the opportunity of studying this case for some time. Its history is best given in the language of Dr. Fuller and Dr. Woodward, *internes* at Bellevue Hospital. Dr. Woodward says:

"The patient, Henry Elsmán, nine years old, a native of the United States, was admitted into Ward 7 November 9, 1882, for a compound fracture of the right tibia. The fracture was treated with a plaster splint, and the wound was sealed up with cotton and collodion. The patient's temperature was highest on the day of his admission, 100.1° F. After November 10th the temperature range was from 96.2° to less than 100°. When admitted, the patient presented no eruption on his body, and no enlarged glands were noticed.

"In the history-book it is stated that on the 15th an eruption had been noticed on his body for a few days before, and was recognized as a secondary syphilide. The precise date when the eruption appeared can not be obtained. Judging from the circumstances which I know existed at the time, I think it was about the 12th of November that the nurse called my attention to an eruption on the patient's body. I happened to be notified of the eruption before any other member of the staff. The eruption was then confined almost entirely to the chest, and was quite pale. Three days later Dr. McBurney pronounced the case one of syphilis, and on that day the lesions in the throat were discovered. On the 12th the glands in the left side of the neck were very much enlarged, and the patient told me that

they had been so for a "long time." The glands on the right side were not much changed in size from normal. November 15th the initial lesion was discovered on the left tonsil, as stated before. From the beginning the patient has had no sore throat, no loss of hair at any time, and no constitutional disturbance. The treatment has been by one sixty-fourth of a grain of corrosive sublimate three times a day, by the month, iodoform being applied to the left tonsil. December 5th inunctions of the oleate of mercury were begun. January 3d it was noted that no iodoform had been applied for about two weeks; the other treatment had been continued."

Dr. Fuller writes: "Accept my apology for the delay in sending you the particulars of the history in the case of the boy Elsmán whom you saw in Ward 7 lately. At best, they are very meager. He says that one afternoon, as he was returning from school, in Vandewater Street—the date he can not give, or even guess at—he was induced to show a strange man the way to the water-closet. The compensation for this information, or guidance, was five cents. He says that, while in the water-closet, he was induced twice (at the same time) to submit to the attention of the man, the evidence of which he has at present in his throat. There was no other boy with him, the man was a stranger to him, and this occasion was the first and last of its kind. He says he can show me the water-closet, which is in Chatham Street, and further says that he and the man were surprised by a woman who lives in the house to which the water-closet is an attachment. At this date (December 5th) the eruption is well developed on his face and head, as well as the body. The pharyngeal ulcer is nearly healed."

My friend, Dr. G. H. Fox, sent for my inspection a man who was also infected on the left tonsil as a result of depraved habits with women.

I have now under my care a young woman, suffering from a tubercular syphilide, whose syphilis began on the left tonsil. She narrates with great minuteness the mode of contagion from unnatural practices with a lover. She had, at the time of her tonsillar chancre, difficulty of swallowing, with some pain and swelling of the glands.

My friend Dr. E. Wigglesworth, of Boston, has sent me the following case:

"An enthusiastic medical student, now a physician, delivered, May 14th, 1879, an Irish woman of a child unconscious and apparently asphyxiated. With his own breath—mouth to mouth—he inflated the lungs of the child several times, but in vain. He then rinsed his mouth with gin, from a bottle belonging to the woman, having used some from the same bottle previously to rub the child's back.

"A month later, June 14th, he noticed a sore upon the right tonsil. This he burnt with nitrate of silver. The sore grew worse; the tonsil swelled; eating or drinking caused great pain.

"July 3d the hypertrophied tonsil and the elongated uvula were both cut off. The whole cut surface ulcerated. The right side of the neck swelled to a large lump involving the glands beneath the jaw and ear. The pain in swallowing increased, and there was some difficulty in breathing. This condition improved after the application of leeches. There was insomnia. A fortnight at the sea-shore caused no improvement.

"Toward the end of July there appeared a pretty general eruption of papules, in some cases with slight pustulation, over the back, arms, and legs, and afterward upon the face, and a few on the scalp, accompanied by malaise, some fever, headache, pains in the knees, and lassitude. There was loss of hair, not only from the scalp, but also from the eyebrows

and eye-lashes, all of which was subsequently regained after treatment.

"Still unsuspicious, or at all events unconvinced by these symptoms, the patient delayed consulting me until the 23d of August. He was put at once upon mercurial treatment, with tonics; hygiene, great cleanliness, baths, and nourishing food were ordered, and drinking was prohibited. The only other symptoms were a mucous patch on the larynx and one upon the lower jaw. Improvement was rapid. The symptoms all disappeared. Treatment was continued for two years and a half, with intermissions. Then he took iodide of potassium for six months. There were no relapses, except possibly a slight mydriasis of the right eye, occurring last October, during my absence from the country, and yielding speedily to potassic iodide. There were no other lesions. The glands in the groins were never swollen, nor those of the elbows."

My late colleague, Dr. Bumstead, narrated at great length to me a case of chancre of the tonsil which was contracted by a man as a result of an unnatural and beastly practice.

Schirajew* reports two cases.

The first was that of a woman, twenty-eight years old, who had redness, swelling, induration, and exulceration of the left tonsil, which was afterward covered with a grayish-white exudation. There was indolent swelling of the ganglia. In due time she had general manifestations of syphilis.

The second case was that of a mother, whose child was infected by its nurse, who was infected on the left tonsil by the infant.

Spilmann† reports the case of a woman, of good health and irreproachable habits, who consulted him for slight sore throat and ganglionic enlargement at the right maxillary angle. On the left tonsil was a superficially ulcerated patch, of the size of a cent, covered with a whitish-gray film. The parotid gland of the same side was enlarged and painful. Later on, general manifestations appeared. Infection in this case was traced to contact with a nursing-bottle of a syphilitic child. The woman did not have any lesion of the genitals.

Hulot‡ reports the following cases: 1. That of a married woman, twenty-seven years of age, of good constitution, who had on the left tonsil an ulcer, red, swollen, and indurated. The left pillar of the fauces was also involved. The corresponding ganglia were enlarged. Her infection came from a chancre of the mouth of a friend's child, which she was in the habit of kissing. 2. A man, twenty-three years old, had an ulceration, irregular and uneven, on the right tonsil, which was covered with a whitish film, under which there was a reddened base. There was marked induration, the corresponding ganglia were enlarged, and syphilis appeared later on. The man could give no account of the mode of contagion. His habits were none of the best. 3. A woman having chancre of the right tonsil, caused by kissing her daughter, who had mucous patches in the mouth. 4. A woman, married, thirty years of age, had a chancre on the right tonsil, contracted from her daughter, who had a similar lesion on the neck. She afterward developed syphilis.

O. Boeck* gives the details of four cases of tonsillar syphilis, in two of which infection occurred from the use of eating

and drinking vessels, and the third from a kiss. In the fourth the origin was not discovered.

The clinical history of these chancres is as follows: The first appearances noted are redness and swelling, without perceptible induration. In the course of a few days these symptoms are accentuated, the redness is greater, the hypertrophy is more marked, and there is also superficial erosion of the organ. Then this exulceration may increase, and is usually accompanied by the appearance of a grayish-white coating, which may be very thin or thicker, and may be of granular appearance and irregularly distributed over the ulcer. The induration is usually well marked, sometimes even cartilaginous. It, of course, differs in accordance with the density of the tonsil. If the latter has been the seat of chronic hypertrophy, it will be hard and firm; if it was previously healthy, it may only be slightly indurated. The prominence of the organ in disease will in a measure also depend on its size and condition previous to infection.

The diagnosis rests between mucous patches and syphilitic ulcerated, sclerosed tonsils, in both of which the lesions will not be so sharply confined to one side, nor accompanied by such well-marked adenopathy. Again, the history of the case will often establish the late origin of the lesions. The subjective symptoms are more or less difficulty in swallowing, perhaps pain, and uneasiness on the affected side, swelling of the corresponding glands, parotid and submaxillary, and of the lymphatic ganglia. This swelling, besides being at first unilateral, is always out of proportion to that observed to accompany secondary and tertiary lesions.

The points of diagnosis are as follows:

1. The details of the mode of infection, either from syphilitic sores, primary or secondary, chiefly about the mouth or face, and mostly by kissing; from infection by some article, such as a nursing-bottle, cigar, pipe, cup, or the like; or from indulgence in bestial practices.
2. The slow, unilateral development of the chancre, with corresponding gland and ganglion enlargement, so well marked.
3. The limitation of the lesion to the affected side.
4. The difficulty in deglutition, and even pain, which is referred to one side.
5. The history of the evolution of the syphilis, the absence of chancre from other parts, especially the genitals, and the much less indurated condition of the ganglia seated elsewhere. Those that are seated at a distance may not be affected until near the date of the evolution of secondary manifestations.

A CASE OF

CHRONIC DISEASE OF THE MASTOID ANTRUM,

WITH OBSTRUCTED OUTLET FOR THE DISCHARGE, ILLUSTRATING THE VALUE OF WELL-TIMED OPERATIVE INTERFERENCE AND THE IMPORTANCE OF THOROUGH CLEANSING OF THE EAR BY DOUCHE OR SYRINGE.

By HUNTINGTON RICHARDS, M. D.,

ASSISTANT SURGEON AT THE NEW YORK EYE AND EAR INFIRMARY.

The history of the following case is condensed and in part quoted from detailed notes taken throughout the course

* "Harte Schanker an der Tonsillen," "Petersburg. med. Wochenschrift," 39, 1880, and "Vierteljahresschrift für Dermatologie und Syphilis," 13, 126, 1881.

† "Contribution à l'étude du chancre buccal," "Annales de dermatologie et de syphiligraphie," x, 1880, p. 78.

of treatment. The patient, a young lady, aged fifteen years, had been the subject of purulent disease of the middle ear for the period of twelve years, or ever since she was three years old.

Previous History.—The patient has never had scarlatina or diphtheria, and says that she is not subject to attacks of sore throat. In the winter of 1871 she had measles, followed, after an interval of two months, by pain in the right ear, which lasted for several days, until the establishment of an aural discharge. Ever since that time she has been subject to attacks of pain in the same ear, alternating with otorrhea, such attacks recurring about once every twelve months. Pain and otorrhea have never been co-existent. The usual duration of these otalgic periods has been about four days. Some fifteen months ago she had an attack of pain which lasted considerably longer—viz., one month. A polyp was then removed from the ear, its removal having apparently brought about a cessation of the long-lasting pain. She has noticed a bad odor to the discharge only during the past four years.

May 2, 1883.—At the request of her physician, Dr. Buechler, of this city, the patient was seen by Dr. Albert H. Buck, from whose case-book I abstract the following brief notes: "Chronic discharge from right ear. Pain for several days past, increasing in severity. No discharge since yesterday." Dr. Buck found a prolapse of the upper wall of the external auditory canal, almost obliterating the canal and entirely preventing a view of its deeper parts. He syringed out the canal, using for this purpose a slender, straight glass nozzle introduced beyond the obstructing prolapse, and ordered the use of poultices at home and complete rest. On the following day Dr. Buck incised the prolapsed wall down to the bone, evacuating a considerable quantity of foul pus interspersed with small masses of cheesy material. By aid of the bent probe and curette several large masses of this material were extracted, showing that there was undoubtedly more of it lodged somewhere in the deeper parts of the ear. On the next day Dr. Buck noted as follows: "Perfectly comfortable night. Free discharge." Three days later (7th) the pain was beginning to return, and the discharge diminishing in amount. The cleansing of the ear was performed daily with the slender glass nozzle at the office, it being quite out of the question for the patient to succeed in doing it herself with any form of syringe or douche.

8th.—Dr. Buck noted as follows: "Sleepless night. Very little discharge. Much pain, referred to back of head generally, and also to deeper part of ear. No appreciable localization of the pain behind the ear; no redness and no tenderness of the mastoid integuments. Temperature, 100° F. As my attempts to overcome the obstructions existing in the external auditory canal seemed not only to fail of accomplishing their purpose, but rather to aggravate the active inflammation of the entire region, I decided to establish an artificial opening through the probably sclerosed mastoid process. Patient etherized. An obtuse-angled incision made. No arterial hemorrhage. Periosteum pushed forward until edge of meatus was exposed, and then applied drill above and a little behind orifice. Bone found to be solid, but not excessively hard, for a distance of half an inch. At this depth the drill (6 mm. in diameter) encountered some resistance, and I withdrew it from the opening in the bone. On introducing a slender probe, I found that at the bottom of the artificial channel there was a small opening, perhaps a millimetre in diameter, through which the instrument passed onward, without meeting any resistance, for a distance of another half inch. This latter cavity was undoubtedly the antrum. By a careful use of the drill I was able to ream out this narrow opening until it measured fully two millimetres in diameter,

this cautious use of the drill being rendered necessary by the danger, which is by no means imaginary, of splitting the temporal bone. Soon afterward, when the patient began to vomit from the effects of the ether, rich pus welled up from the opening in the bone. Wound syringed out with a strong solution of carbolic acid, and external wound left gaping." From this time on the care of the case was committed to the writer of this article, and it progressed as follows:

9th.—Patient passed a fairly comfortable night, having no pain. The removal of the dressings was attended by a good deal of pain and by considerable hemorrhage, due to the probable nicking of a small arterial branch at lower angle of incision during the operation. Pus found lying in external auditory canal, and also, on removal of dressings, seen issuing from the opening in the bone. On account of the bleeding, no attempt was made at this time to syringe out the channel in the bone, and the wound was filled with lint well coated with vaseline. Patient revisited at 9.30 p. m. No further hemorrhage. No pain. Temperature, 100° F.; pulse, 100.

10th.—Dressings removed; surface of wound rather sloughy; no hemorrhage; sinus in bone syringed with carbolized water (1 to 20); no return current through external auditory canal. Lint, smeared with borated vaseline, was applied to surface of wound, over this a layer of carbolated lint, and as outside dressing a thick layer of oakum held in place by a bandage. The patient has no pain, but there is some stiffness of the cords of the neck (right side). Tongue clean; some appetite; temperature 100.5° F., pulse 118.

11th.—By means of a Hartmann's nozzle, straightened at its point and attached to a Davidson's syringe, the sinus in the bone was thoroughly sluiced with carbolized water, and the external auditory canal was cleansed with borated water (a common ear-syringe being used for this purpose); wound dressed as on May 10th; patient has no pain; she looks and feels much better; temperature 100° F., pulse 100; discharge moderate in amount and smells less badly than it did yesterday; considerable swelling below wound in region of parotid gland.

12th.—Less swelling below the wound; surface of wound looks cleaner; the bad smell, noticed May 10th and 11th, in the dressings removed, has now decidedly diminished; temperature 100° F., pulse 102; wound dressed as yesterday.

13th.—The patient sitting up; no headache and no pain about the ear; the wound looks well and the glandular swelling below it has almost entirely disappeared; the stiffness of the right side of neck, observed on May 10th, has diminished, but the patient notices a slight stiffness on the left side; temperature 99.4° F., pulse 120; scarcely any bad smell to dressings removed. Substituting a saturated solution of boric acid for the carbolized water hitherto employed, I syringed the wound and bone sinus with the usual degree of force, and for the first time succeeded in getting a return of the fluid through the external auditory canal, although only to the extent of a few drops. The syringing caused a slight and very transitory sensation of pain and of fullness in the ear. Examination of the external auditory canal by reflected light showed its lining membrane of a pale-red color; no view of deeper parts of canal, as the obstruction was still too great, but I succeeded in slowly passing a probe wrapped with cotton past the obstructing prolapsed wall and down to the estimated level of the annulus tympanicus. This manoeuvre caused the patient no pain. The usual dressings were applied to the wound, a cap being substituted for the retaining bandage.

14th.—The patient has had rather a poor night, and complains to-day of slight sore throat. Temperature 101.9° F., pulse 120; tongue furred; bowels regular. Examination of the throat shows a slight exacerbation of a chronic pharyngitis, and, in

addition, mild follicular inflammation of the right tonsil. Ordered care in diet, a soda gargle, and quin. sulph., gr. vj, at bedtime, the latter to be continued hereafter in doses of gr. ij, t. i. d. Usual dressings applied; no return current obtained through the meatus when the bone sinus was syringed (yesterday's very gentle exploration of the auditory canal had probably sufficed to increase the swelling of its walls).

15th.—Patient had a better night; throat less sore and tongue cleaner. Temperature 101-9° F., pulse 180. She says she had slight pain in one elbow and in one of her wrists yesterday; none to-day. Quin. sulph. to be increased to gr. x at bedtime to-night, and gr. iv, t. i. d., hereafter. Usual dressing and syringing, but no return current through the ear. The wound is discharging healthy pus, and the discharge is more abundant.

16th.—The patient feels better and has decided appetite. Tongue fairly clean. Temperature 99-4° F., pulse 100. Wound looks healthy and is discharging freely. Return current through the ear re-established when the bone sinus is syringed. A rubber-capped and tightly fitting nozzle introduced in the auditory meatus and the ear syringed in the reverse direction, with the result of causing the current to emerge through the wound, and also, in part, through the patient's nose by way of the Eustachian tube.

17th.—Temperature 98-7° F., pulse 102. There is no more sore throat, and the patient states that she has had no pain in the ear, nor any headache "of any account," since the operation on May 8th. Ear syringed as yesterday, but with a different result, a return current being only established during the use of the closely fitting nozzle in the meatus, the Hartmann's nozzle being so much smaller than the caliber of the sinus in the mastoid process that much of the force of the current is lost.

18th.—Temperature 99° F., pulse 112. Patient allowed to go out of doors for a short time.

19th.—Temperature 98-4° F. No attempt made to syringe through the sinus, and, in using the syringe in the meatus, I substituted the slender Hartmann's nozzle for the larger obturating nozzle hitherto employed; as a result, a few drops of the borated water returned through the sinus, and a considerable quantity through the Eustachian tube.

20th-23d.—Same dressing and same method of syringing as on May 19th.

24th.—Patient came to the office. Thinking it possible that the Hartmann's nozzle, as used in the external auditory canal, might have a share in keeping up the swelling in the walls of the latter, I substituted for it to-day the less irritating short-pronged nozzle of the "Angelo douche"; the patient to use the same nozzle at home, attaching it to a gravitation douche having its reservoir suspended eight or nine feet above the floor.

26th.—Temperature 98-2° F. Quinine reduced to gr. ij, t. i. d. External auditory canal more patulous. Small flakes of curdy pus brought away by the return current through the sinus. Contrary to what was observed some time ago, the chief swelling in the auditory canal is now along the anterior and inferior wall.

June 1st.—The patient uses the gravitation douche twice a day. Examination by reflected light shows the canal so free that a fair view can be had of its deeper parts. A large polyp seen lying in the tympanic cavity. Profuse, badly smelling discharge lying in the auditory canal to-day, and so the douche ordered to be used more frequently.

From this time until June 23d the patient was seen at the office about once every three or four days. By June 11th, the external auditory canal having become sufficiently roomy for such manoeuvres, a considerable portion of the polyp was removed by Blake's snare; another smaller portion was similarly removed on June 16th. On June 9th it was noted that the wound behind the ear had become a mere line of granulations

about half an inch long, and the discharge from it was so slight in amount that by June 11th it was found scabbed over. This scab, however, had fallen off by June 16th, and again there was a slight discharge from the mouth of the sinus it had covered; a free return current also took place through this sinus when the ear was syringed. (Careful examination of the patient's nose and throat having revealed the customary lesions of chronic naso-pharyngeal catarrh of the hypertrophic variety, she was put upon a systematic course of local treatment for this condition, such treatment being begun on June 1st.)*

On June 23d the scab had reformed, but exploration with a probe demonstrated that the sinus was still pervious, and, when the ear was syringed, a few drops of the borated water were seen to trickle from its mouth. The caliber of the auditory canal had greatly increased, and, the general condition of the ear seeming to warrant it, I allowed the patient to leave town and go to the country for a week. The tonic dose of quinine was discontinued, but she was directed to persist in the use of the cod-liver oil (3 j, t. i. d.), which had been ordered a few days previously. On July 2d she returned to town looking extremely well, with good, healthy color, and reporting that she had experienced no discomfort about the ear. There was free discharge from the external auditory canal, and slight discharge from the sinus. A probe detected bare bone around the margin of the aural polyp, a considerable portion of which latter was again removed by the snare, and the patient was permitted to return to the country for another week, it being distinctly understood that, upon the supervention of any bad symptoms, she was to report at once for examination.

About the middle of July the external auditory canal again became stenosed, and a separating sequestrum was detected in the tympanic cavity (July 10th and 17th), its attachments, however, being too firm to admit of its removal. This sequestrum came away spontaneously July 19th, and, from its shape, I judged it to be a portion of the anulus tympanicus. On July 22d the discharge stopped, and for the first time since the operation the patient experienced decided pain in the ear; this pain, however, was of short duration, being quickly relieved by frequently repeated douchings of warm water. Next day the patient came to the city, and I found the auditory canal almost closed from sagging of its walls; the sinus behind the ear was firmly and,

* The details of this treatment it is not necessary to give, but one point observed during the examinations of the throat may be worthy of mention, as showing a decided connection between the pharyngeal lesions and the suppurative disease in the ear. Besides the presence of markedly enlarged tonsils and of a general hypertrophy affecting the mucous membrane of the anterior and posterior nares and of the entire pharynx, it was very noticeable that the chief amount of the pharyngeal hypertrophy existed on the right side, a long band of pale, yellowish-red, very soft and flabby mucous tissue running perpendicularly down this wall of the pharynx, while no such corresponding band existed on the other side. In view of the decidedly patulous condition of the right Eustachian canal (a condition abundantly demonstrated during the syringings of the ear), it is not unreasonable to suppose that a constant leakage of foul pus was the prime factor in producing so unusually marked a degree of hypertrophy on this side of the pharynx. The reasonableness of this supposition was further confirmed by the subsequent progress of the throat lesions; thus, on August 8th, the external auditory canal having become very much larger in its caliber, the aural discharge being reduced to a minimum, and the sinus behind the ear having long remained permanently closed, it was noted that this peculiar band of thickened tissue had disappeared, while the hypertrophy in other parts of the pharynx, in spite of the local and general treatment employed, had undergone, by comparison, only a slight degree of improvement. Here, then, we seem to have an instance of a sequence of events not commonly observed—viz., a lesion of the throat caused by disease of the ear.

as the result showed, permanently closed. On syringing with the Hartmann's nozzle, a large quantity of badly smelling caseous matter was evacuated from the drum cavity, and the patient was directed to use her gravitation douche five or six times daily. The next morning she reported that she had had no further pain or discomfort about the ear. Syringing at the office again brought away a large amount of the caseous material, but there was much less stenosis of the auditory canal. On the following day the canal was sufficiently free to allow of my snaring off a portion of the polyp, and the same manoeuvre was repeated July 26th. By this time the amount of caseous matter evacuated by the syringing had become so much less that the patient was allowed to discontinue her visits to the office until July 30th.

July 30th.—I noted as follows: The auditory canal had become more patulous than at any time since the patient first came under observation, permitting a full view of the tympanic cavity. The discharge from the ear had also greatly diminished in amount, and the patient observed that it had less of a disagreeable odor. The polypoidal mass occupying the posterior and lower portion of the drum cavity had shrunken into an irregular shriveled hummock, pale-red in color, and still soft and like granulation tissue at its anterior margin; but backward from this point rapidly increasing in density, and white in color, until it merged into the posterior wall of the external auditory canal at its tympanic orifice. Instead of the straightened Hartmann's nozzle previously employed in syringing the canal, I to-day made use of a slender glass nozzle specially prepared and having an abrupt upward curve at its tip; this nozzle was attached to the Davidson's syringe, and was carefully introduced into the now roomy drum cavity in such a manner that its curved extremity should be directed toward the upper and posterior hidden portion of this cavity. Forebore douching through the nozzle, firmly held in this position, resulted in the evacuation of a few shreddy fragments of epithelium mingled with minute flakes of cheesy pus, the latter also in small amount. The anterior pale-red portion of the now wart-like polyp was touched with the "solid bead" of nitrate of silver, and a little burnt alum was dusted over its surface. The patient was allowed to reduce the number of her douchings at home from five or six down to four daily.

August 2d.—The applications of July 30th were repeated and the ear was similarly syringed, the borated water returning quite clear, except for the presence of a few small flakes of epithelium; no caseous matter. The discharge from the ear had very greatly diminished, and presented hardly a trace of its former bad odor.

6th.—Above and behind the shrunken base of the polyp a probe may be passed into a very roomy space, the posterior portion of the tympanic cavity having evidently become abnormally enlarged. (This very striking expansion of the drum cavity was doubtless the result in part of the carious and necrotic processes which had, as it were, nibbled away its limiting walls. Chiefly, however, may it be ascribed to an absorption of these walls, the effect of pressure exerted upon them by an ever-increasing mass of the caseous material and exfoliated epithelium constituting the characteristic *débris* of a chronic inflammatory process in this region.) Absorbent cotton on a bent probe, passed into this cavity, brings away a small amount of caseous pus. To-day the ear was not syringed, the application of burnt alum alone being made, and the experiment was tried of discontinuing the use of the douche at home.

7th.—Rather more discharge was found lying in the drum cavity and deeper part of the canal, and so the ear was again syringed out as on July 30th and August 2d, and the patient was ordered to use her douche three times daily.

8th.—A small but firmly attached spiculum of bone was seen projecting from the middle of the wart-like hummock in the drum cavity. Usual application of burnt alum was made and the ear insufflated with iodoform. The patient was permitted to go to the Catskill Mountains for three or four weeks, but was enjoined to continue the use of her douche while there.

September 11th.—The patient just returned from the Catskills and in excellent health. She has kept up the use of her douche as directed. A minimum of discharge from the ear and no bad smell. To-day I removed a small blackened spiculum of dead bone from the still persisting hummock of shrunken polypoidal tissue. A decided desquamative process going on in the tympanic cavity. After carefully cleansing the ear by means of the curved glass nozzle, I filled the entire cavity with a warmed solution of nitrate of silver (gr. ijss. to 3j). This solution being allowed to remain in the ear about two minutes (during which time it caused no pain or discomfort by its presence), I washed out the ear with a common syringe, carefully dried all parts of the surface with absorbent cotton, and applied powdered iodoform by cotton-holder and insufflator.

15th, 18th, 22d, and 24th.—Same treatment.

28th.—Increased the strength of the solution of nitrate of silver to gr. v-3j; the patient to douche her ear only twice a day hereafter.

From October 2d to October 23d I was absent from the city, and she was directed during this interval to syringe her ear with the usual borated water every morning, and in the evening, after a preliminary cleansing with pure water, to instill ten drops of the following solution: \mathcal{R} Plumbi subacetat., gr. ij; aq. destillat., 3j.

October 23d.—The patient reported that the antral discharge had entirely ceased. On examination, the drum cavity was seen to be exceedingly roomy, a very cave in fact, and its walls looked smooth, white, and perfectly dry; nevertheless, a probe wrapped with cotton and bent at a right angle near its tip detected a minute quantity of pus lying on the outer wall of the tympanum in the region of the mastoid antrum. The usual applications were made at the office, and repeated at intervals of about four days until November 17th. During this period, besides the customary flooding of the entire cavity with the five-grain solution of nitrate of silver, I directed my attention especially to the point of persisting secretion near the antrum mastoideum, applying to this point, by means of a sharply bent cotton-holder, a solution of much greater strength (gr. xx-3j, and even gr. xlv-3j). On November 17th this obstinate point began to yield, its secretion being reduced to such an infinitesimal quantity that the cleansing of the ear at the patient's home was ordered to be omitted for forty-eight hours. The burnt alum, previously applied by cotton-holder, was to-day mixed with the iodoform, and the mixture was blown in by the insufflator. On November 20th I repeated this insufflation, but omitted the use of the nitrate of silver solutions, and the patient was instructed to let the ear entirely alone and to report for examination.

November 24th.—Finally, on this day the patient was dismissed from treatment and was emancipated from the use of the douche and ear-drops at home, the drum cavity showing no further trace of purulent secretion. The scar left by the operation was very small and was completely covered by the patient's hair, and there was no perceptible displacement of the auricle. A letter from the young lady's father, dated March 6, 1884, reported that her ear was "all right"; she had had no pain; there was no unpleasant odor remaining about the ear; and, there being no discharge from it, the douche had been permanently laid aside.

THE
NEW YORK MEDICAL JOURNAL,
A Weekly Review of Medicine.

NEW YORK, SATURDAY, MAY 24, 1884.

PECUNIARY AID TO MEDICAL COLLEGES.

WE lately suggested a reason for the rarity of gifts of money to medical colleges, namely, the lack of information which might be presumed to exist on the part of wealthy and benevolent persons in regard to the independent basis on which such institutions are generally managed in this country, and to the necessity of giving to them specifically if they are to be benefited by the gift. It must be that some such misapprehension is at the bottom of the apparent disinclination of wealthy persons to confer substantial benefits on the class of schools in question, but no doubt also persons of that sort fail in many instances to appreciate the beneficent effect that would result to the masses from any measure calculated to promote the most efficient teaching of medicine.

Men give freely to hospitals, perhaps because the application of such gifts in the cause of charity is more perceptible, if not more direct. It is difficult to avoid the conclusion that this notion implies a radical misconception of the nature of a hospital. If hospitals were merely retreats where the sick and the injured were to be sheltered and fed, the expensiveness of their administration would be out of all proportion to the objects in view, and it would be much more economical to discontinue them altogether, and multiply and improve our almshouses instead. A hospital is not only a place of shelter; it is also a place where the sick and the injured are to be cured, in so far as it may be practicable, or, that being out of the question, their lives prolonged and their sufferings mitigated. Without depreciating the importance of the auxiliary means to this end, such as good food and good nursing, it can not be questioned that the prime factor in determining the degree in which a hospital will accomplish the purposes for which it was established is the knowledge and skill of its medical staff. As medical science advances, patients are cured who, ten years before, would have been looked upon as inevitably doomed to speedy death, or at least to enduring disability and misery. The more the advance of medicine is promoted, the greater will be the proportion of persons benefited by its ministrations.

It may be said that a reciprocal action is going on, that hospital work necessarily advances the art of medicine. This is undeniably true, but it is not the whole story—it is not alone, or chiefly, by the observation of disease that medical progress is accomplished; it is rather by the systematic study of the fundamental branches, by laboratory work, by work which at the time may seem to have but a remote connection with the treatment of disease. Now, research of this sort is not self-sustaining, and in no considerable degree do the studies of the investigator aid him in the task of making a living. Those who

build up the science that flowers into the art of medicine should be men who are free from the constant need of taking thought as to their own maintenance and that of their families. With that freedom secured to them, they may not, it is true, cure a single patient in the whole course of their lives, but they may, nevertheless, be the means of enabling practitioners of the art of medicine to extend the benefits of that art immeasurably.

Those branches of the medical curriculum, therefore, which call for continuous research and for the use of expensive adjuncts to teaching ought to be provided for by pecuniary aid from the laity. Who gives for such a purpose gives not to benefit the members of the medical profession, but to benefit the community, himself included. What are called the practical branches, however, do not seem to stand in need of any such provision; indeed, it may be questioned if the endowment of a medical college as a whole is a good thing. Practical medicine and surgery and obstetrics are best taught by men who are engaged in the active practice of those branches—in homely phrase, by those whose bread and butter depend on their practice and their teaching. It is true of most men that nothing but the need of the "almighty dollar" will draw out their best work. Give a man to understand that his income from teaching is to depend on his ability to satisfy the students' demands for knowledge, and he will exert himself to the utmost; but put him on a salary, and he stagnates. From these considerations, those who make gifts to medical colleges are doubtless wise in specifying the particular use to which the money is to be put, as was done in the case of a recent benefaction to Bellevue Hospital Medical College.

RECTAL ETHERIZATION.

ON more than one occasion we have cautioned our readers in regard to the indiscriminate trial of therapeutic novelties. Thus far, we have refrained from mentioning the practice of anæsthetization with ether introduced by way of the rectum, lately proposed by M. Mollière, of Lyons, but it has now been tried in a number of cases in New York, with such results that, while they point to certain features of excellence, seem to call for a renewal of the caution alluded to.

It is no more than fair to say, at the outset, that the method promises very substantial benefits. These benefits are, in the inverse order of their importance, the saving of ether and the avoidance of the preliminary strangling and struggling which are so trying to the patient and the surgeon in the production of anæsthetization by the inhalation of ether. In regard to the saving of ether, we do not understand that those who favor the method profess that less of the drug is actually introduced into the system, but only that none of what is used is lost. If this statement is correct, the advantage of the practice, so far as the consumption of ether is concerned, is a paltry matter of economy, not for an instant to be weighed against any danger which may attend it. The other good feature alleged for the method seems well attested; in almost all instances the patient has gradually and with reasonable promptness fallen into a state resembling natural sleep, preceded by little if any exhalation,

and of course by none of the laryngeal irritation so commonly seen during the early stage of the inhalation of the vapor of ether. Curiously enough, in one instance that has come to our knowledge the rectal administration failed utterly, although the trial was prolonged for as much as twenty minutes, at the end of which time the patient was as wide awake as at the start, and the attempt had to be abandoned. Barring such an exceptional case, it is obvious that the method does away with some of the chief objections to the use of ether as an anæsthetic, and, besides, that it enables anæsthesia to be used in certain operations about the face and throat where inhalation is usually found very inconvenient and sometimes impracticable. There seems to be an impression, too, although we have not heard the statement made in positive terms, that there is apt to be less nausea after the patient has emerged from the anæsthesia than when the inhalation method has been employed. If this should prove to be the case, the new practice must certainly be credited with an additional advantage of no slight importance.

Unfortunately, the method is not without its dangers, as shown by the fact that it has given rise to at least two deaths during the few weeks that it has been on trial in New York. This should not lead to its hasty condemnation, but most assuredly it should emphasize the caution with which it is to be employed, as well as the necessity of so improving the technics of the procedure as to draw from it as many as possible of its advantages with the utmost attainable avoidance of its dangers. The two deaths to which we have referred are attributed to intestinal irritation, and it is worthy of remark that in many instances that have not proved fatal such irritation has been observed. One of the deaths was that of a child, and there is a feeling with some of those who have made use of the method that it is not appropriate in the case of children, since there is reason to think that the mere distension of the intestine sometimes produced by the vapor, quite apart from an irritant action, is apt to be followed by serious results in children. In the other fatal case, that of a woman whose general health was not known to be impaired, the anæsthesia was induced for so trifling a procedure as the cauterization of a chancreoid, and after death the whole large intestine, together with the lower part of the small intestine, was found in a state of acute ulceration.

It is to be noted that some of the gentlemen who have tried the method have witnessed intestinal irritation in almost all their patients, while others have found it quite the exception. The inference is drawn that in the one case sufficient precautions were not taken to guard against the injection of liquid ether into the rectum. It is recommended, therefore, that the apparatus employed should be such as not to allow of this occurrence, and, in particular, that the tube leading from the ether receptacle should not be long enough to afford an opportunity for the vapor to condense before it enters the intestinal canal. It is considered desirable, too, that the bowels should be cleared out by means of an enema before the administration is begun; but this precaution, we take it, bears rather upon the efficiency of the practice than upon the avoidance of danger. It is to be hoped that careful attention to some such matters of detail as

we have indicated will render the method practically as free from danger as that by inhalation. Until that state of things is assured, we must insist on the need of great discrimination in the employment of anæsthetization by the rectum.

THE MECHANICS OF THE BRAIN.

We lately summarized some remarkable statements made by M. Luys before the Paris *Académie de médecine*, the purport of which was that the brain underwent certain movements within the skull in accordance with changes in the attitude of the body, those movements being provided for by the existence of an "empty space" between the brain and the skull. At the outset, M. Luys's ideas encountered sharp opposition, and the discussion has been continued at various meetings of the academy. At a recent meeting, reported in the "*Gazette hebdomadaire de médecine et de chirurgie*," M. Luys brought forward fresh arguments in support of his position. He stated that he had placed a cadaver in the upright posture, and had then made a hole in the vault of the cranium, through which he injected a substance capable of coagulating, and finally made a counter-opening in the lower part of the skull, for the purpose of draining off the cerebro-spinal fluid. After this the cranium was laid open, and it was observed that the material that had been injected occupied chiefly the superior part of the convolutions. On varying the experiment by placing the cadaver on the back, the greater thickness of the solidified material was found seated over the frontal lobes. All this proves, in his opinion, that the brain, being smaller than the cranial cavity, always tends to sink downward, leaving at the upper portion, varying with the attitude, a free space demonstrated by the greater thickness of the injected matter, this free space being estimated at about one eleventh the volume of the brain.

Arguing particularly from the pathological standpoint, M. Trélat combated M. Luys's position, calling attention to the fact that the brain was so arranged as to undergo the least possible effect from the mere action of gravity, whether occasioned by changes of attitude or by jars of the head, and to escape the consequences of variations of pressure dependent on respiration, arterial diastole, or depletion of the sinuses by changes of position or muscular exertion. Under normal conditions, the blood in the sinuses and the venous plexuses on the one hand, and the cerebro-spinal fluid on the other, were the agents of this preservative mechanism; so that the movements of the cerebral mass, thanks to the arachnoid, were limited to slight variations of tension on the part of the brain or its envelopes. Consequently, if the mechanism portrayed by M. Luys were founded in fact, contusions and attritions of the brain would be frequent; yet, as a matter of fact, considerable force was required to produce such a result.

Whenever the movements described by M. Luys took place, the conditions were pathological, and he could not admit the force of experiments on the cadaver, for there was apt to be a disappearance or diminution of the cerebro-spinal fluid, or absence or coagulation of the venous blood. It was a question if we could admit that the injection of a coagulable material into

the arteries re-established the conditions that obtained during life. Pathological observations by Broca and Verneuil showed only that the encephalon underwent variations of pressure, the sources of which were known; we could not infer that the brain was capable of displacement as a whole.

M. Sappey admitted M. Luys's facts, but differed with him as to their interpretation. The weight of the brain, he said, was not so great as was commonly stated. Its anatomical weight was not usually more than 1,350 grammes, while its physiological weight, meaning its weight as it floated in the cerebro-spinal fluid, was about 45 grammes on an average—about one thirty-eighth of its anatomical weight. Although it was generally supposed that the cerebro-spinal fluid was spread out evenly over the surface of the brain, he did not share in this view; the brain sank to the base of the skull, on which it rested, and the fluid accumulated mainly over the surface of the hemispheres, in a layer averaging about 5 mm. in thickness. To determine whether, as maintained by M. Luys, the brain left the base of the skull when the attitude was changed, he had opened the cranium at the base, instead of at the vault; having opened the spinal canal, and so arranged the meninges that the cerebro-spinal fluid could not escape, he had caused the subject to rest on the vault of the cranium, and, after removing the face and exposing the base of the skull, he had made little openings in the roof of the orbit, and then at the level of the sphenoidal fossæ; and, no matter what the attitude might be, the brain did not leave the base of the cranium until the cerebro-spinal fluid was drawn off.

MINOR PARAGRAPHS.

THE PASSENGER SHIP MEDICAL SERVICE BILL.

We are informed that the bill has been so amended by the committee having it in charge as to require the sanitary reports of medical officers to be made to the Port Physician or Health Officer of the port of entry, as a necessary prerequisite for the granting of pratique. It was very pertinently suggested at the recent meeting of the American Medical Association that a sanitary report made to the captain or master alone would never leave his office, and that one made to the owners of a vessel, if condemnatory, would merely lead to the surgeon's discharge. The amended bill also provides a more serious penalty than a fine of two or three hundred dollars, which would be a mere bagatelle to a wealthy corporation.

THE SOCIAL ELEMENT AT THE WASHINGTON MEETING.

A RESIDENT of Washington writes to us as follows: "The usual disgraceful performances took place at the receptions. Mrs. L. generously opened her beautiful house, and provided as fine a table as Demenet could serve. She was rewarded by having men stalk in (hats on their heads) from the front room to the dining-room, where they fought like wolves for places at the tables, overturning piles of plates, breaking her expensive ornaments, and soiling her rugs with pools of tobacco-juice."

We all know that a small army of hangers-on attend the meetings of the American Medical Association, and that most of these fellows manage to get cards admitting them to the receptions, where their boorishness tends to bring the association into discredit. In view of these facts, it seems to us that

the interest of the profession would be furthered if measures were taken to put a stop to the admission of these interlopers.

THE INDISCRIMINATE SALE OF POISONS.

We have frequently called attention to the unwarrantable and dangerous freedom with which poisons of various sorts were to be had by the public. We learn from Dr. F. E. Daniel, of the "Texas Courier-Record of Medicine," who introduced most commendable resolutions bearing upon the subject at the recent meeting of the American Medical Association, that Dr. Henry F. Campbell, the new president of the association, told him at the meeting that he was himself cognizant of a great number of cases of stricture of the œsophagus due to swallowing "concentrated lye," a preparation which is to be had by any purchaser. It was toward restricting the sale of this preparation and that of the domestic potash ball that Dr. Daniel's resolutions were directed.

A KNOWING WITNESS.

At a recent trial in this city a medical "expert" was examined in regard to certain points in neurology. In the cross-examination he was asked if he recognized a particular book as authority in the matter, and the question was repeated in regard to another book, and then another. His answers were to the effect that he was familiar with all the books mentioned, and that they were authorities on the matters alluded to. The medical witness was then allowed to leave the stand, and the lawyer's clerk was sworn, who testified that the titles of the works in question were fictitious, having been concocted in the law office to which he was attached.

LUSK'S "MIDWIFERY" IN SPANISH.

THE "Revista de Medicina y Cirugía Prácticas," one of the best of the Spanish medical journals, follows the policy of furnishing the profession with separate monthly publications, in book form, for a small annual payment. They have the advantage over the "libraries" published in this country that the individual monthly parts may be bought. The February issue consists of the first 176 pages of an excellent translation of Professor Lusk's "Midwifery." The print is very clear and agreeable, and the illustrations, although not so well executed as those of the American edition, are fair.

NEWS ITEMS, ETC.

INFECTIOUS DISEASES IN NEW YORK.—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending May 20, 1884:

DISEASES.	Week ending May 13.		Week ending May 20.	
	Cases.	Deaths.	Cases.	Deaths.
Typhus.....	9	3	4	3
Typhoid Fever.....	10	4	4	1
Scarlet Fever.....	80	17	99	15
Cerebro-spinal meningitis....	4	3	6	4
Measles.....	131	17	94	13
Diphtheria.....	48	18	30	17
Small-pox.....	1	0	0	0

THE NEW BUILDING FOR THE GERMAN DISPENSARY, the gift of the late Mrs. Oswald Ottendorfer, will be opened with appropriate ceremonies this afternoon, at half past three o'clock. The programme, interspersed with songs by representatives of the Liederkranz and the Arion societies, includes a presentation speech, by Mr. Ottendorfer; a speech of acceptance, in behalf

of the German Hospital and Dispensary, by Mr. Kilian; an address in the name of the medical staff, by Dr. A. Caillet; and a discourse by Dr. A. Jacobi. On Sunday afternoon the building, which is situated at No. 137 Second Avenue, will be open to visitors having cards of invitation. In a building adjoining the dispensary, Mr. Ottendorfer has generously provided quarters for a branch of the New York Free Circulating Library, with a reading-room, and has given 8,000 volumes, half in English and half in German, to the library, together with a considerable sum of money.

AN INTERESTING SURGICAL DEMONSTRATION was given by Dr. William F. Fluhner on Thursday afternoon in the amphitheatre of Bellevue Hospital, a patient being shown upon whom Dr. Fluhner had performed successfully the operation of removing a pistol-ball from the brain through a counter-opening in the skull.

THE UNIVERSITY OF THE CITY OF NEW YORK.—We understand that appointments to clinical lectureships in the medical department have lately been made as follows: Dr. Henry G. Piffard, diseases of the skin; Dr. P. A. Morrow, venereal diseases; and Dr. Newton M. Shaffer, orthopaedic surgery.

THE LONG ISLAND COLLEGE HOSPITAL held its twenty-fifth annual commencement on Wednesday evening, the 21st inst., at the Brooklyn Academy of Music, when the degree of doctor of medicine was conferred on a class of forty-four graduates.

THE AMERICAN NEUROLOGICAL ASSOCIATION will hold its tenth annual meeting in New York on Wednesday, Thursday, and Friday, June 18th, 19th, and 20th. Papers are expected to be read by Dr. Waiton, Dr. Putnam, and Dr. Webber, of Boston, and by Dr. Rockwell and Dr. Seguin, of New York.

THE "MEDICAL BULLETIN," of Philadelphia, is to be published hereafter by F. A. Davis, attorney. The editor, Dr. John V. Shoemaker, remarks that this arrangement will enable him to "give still more attention to the reading columns." During the recent meeting of the Medical Society of the State of Pennsylvania the "Bulletin" was issued daily. "In furnishing this daily edition of a medical journal," says the publisher, "we make the first departure of the kind in the history of Philadelphia and the second in that of the world." The latter statement is erroneous, but the enterprise of the "Bulletin" is to be commended, nevertheless.

DR. KOCH, according to the "British Medical Journal," is shortly to be given a professorship in the University of Berlin.

THE INTERNATIONAL HEALTH EXHIBITION was opened in London on the 8th inst., and, according to the accounts in our English contemporaries, with the greatest promise of being made most useful and successful.

BUBONIC PLAGUE, says the "Lancet," is reported to have appeared at Bedra, in the province of Bagdad, and the Porte has ordered a sanitary cordon to be drawn around the infected district.

A HIPPOCRATIC TREE.—The "Lancet" states that, at a recent meeting of a medical society of Berlin, Professor Virchow showed photographs of a gigantic plane-tree that stands in the market-place of the town of Cos, on the island of that name, under the shade of which, as tradition has it, Hippocrates was in the habit of holding medical consultations. The branches now cover nearly the whole market-place, and are supported by marble columns.

THE INCREASE OF THE INSANE BY IMMIGRATION was made the subject of resolutions at the recent meeting of the Association

of Medical Superintendents of American Asylums for the Insane, in which Congress was asked to take measures to check the increase from that source, amounting, it was said, to one third of all the insanity in the country. The present overcrowded state of the Flatbush asylum is reported to be due to the same cause.

RECENT PARIS THESES.—*Thèses de Paris* dated May 8th are announced in the "Progrès médical" as follows: New Methods of Determining the Elements of Milk and its Falsifications, by M. Quesneville; The Melanuric Bilious Fever observed at Mayotte, by M. Vaudein; A Common Point in the Study of the Etiology of Goitre and in that of Typhoid Fever, by M. Dorey; Epileptics, by M. Campart; Movable Articular Bodies and their Treatment, by M. Herland; Tracheotomy in Tuberculous Subjects, by M. Grégoire; and Considerations on the Etiology and Nosological Affinities of Scoury, by M. Lemarchand. Those dated May 10th are: The Rheumatoid Manifestations of Dysentery, by M. Fialho; and The Chorea of Pregnancy, by M. Hervé.

ARMY INTELLIGENCE.—*Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from May 11, 1884, to May 17, 1884:*

WATERS, WILLIAM E., Major and Surgeon. Ordered to report for temporary duty to the commanding officer at Plattsburg Barracks, New York. Par. 4, S. O. 90, Headquarters Department of the East, May 10, 1884.

HUBBARD, VAN BUREN, Major and Surgeon. Relieved from further duty at Fort Stanton, New Mexico, and ordered to Fort Bayard, New Mexico, for duty. Par. 3, S. O. 96, Headquarters Department of the Missouri, May 12, 1884.

MOSELEY, E. B., Captain and Assistant Surgeon. Assigned to temporary duty at Vancouver Barracks, Washington Territory. Par. 6, S. O. 59, Headquarters Department of the Columbia, May 8, 1884.

WILCOX, TIMOTHY E., Captain and Assistant Surgeon. Assigned to duty at Washington Barracks, D. C. Par. 2, S. O. 90, Headquarters Department of the East, May 10, 1884.

WALLES, P. G., First Lieutenant and Assistant Surgeon. Assigned to duty at Old Fort Colville, Washington Territory, until further orders. Par. 3, S. O. 58, Headquarters Department of the Columbia, May 7, 1884.

NAVAL INTELLIGENCE.—*Official List of Changes in the Medical Corps of the Navy during the Week ending May 17, 1884:*

KINDLEBERGER, D., Medical Inspector. To be Fleet Surgeon of the Pacific Station.

LEACH, PHILIP, Assistant Surgeon. Detached from U. S. S. New Hampshire, and ordered to Naval Hospital, Chelsea.

BERTOLETTE, D. N., Passed Assistant Surgeon. Detached from Naval Academy, and ordered to practice ship Date.

SOCIETY MEETINGS FOR THE COMING WEEK.—*Monday, May 26th:* Medical Society of the County of New York.

Tuesday, May 27th: New York Dermatological Society (private); New York Surgical Society; Medical Societies of the Counties of Queens and Rockland, N. Y.; Jersey City Pathological Society; Oregon State Medical Society (Portland—first day).

Wednesday, May 28th: New York Pathological Society; American Microscopical Society of the City of New York; Auburn, N. Y., City Medical Association; Medical Society of the County of Monroe, N. Y.; Connecticut Medical Society (New Haven—first day); Oregon State Medical Society (second day).

Thursday, May 29th: Connecticut Medical Society (second day); Oregon State Medical Society (third day).

Letters to the Editor.

THE STATE SOCIETY'S COMMITTEE ON LEGISLATION.

NEW YORK, April 17, 1884.

To the Editor of the *New York Medical Journal*:

SIR: Your issue of this date contains a letter from Dr. Sturgis criticising the action of the present Committee on Legislation of the State Society, of which committee he was formerly chairman. The gentleman in question has on numerous occasions urged the committee to do its duty, both through your columns and by means of persistent letter-writing to the members of the committee. The criticism of the present committee by its former chairman is, to say the least, in rather bad taste, and perhaps unwise, as I doubt if he can be fully informed as to just what the committee have done, and what they may have neglected to do. The committee itself is responsible solely to the body that appointed it, and the proper time for a review of its work is when its report is presented at the next meeting of the State society. In this connection, however, it may not be improper to state that no fewer than ten objectionable and injurious medical bills were introduced into the Legislature during the session just ended. Of these, six have been killed outright, and four of them amended in a manner satisfactory to the committee. Two of the foregoing bills were introduced a second time, but did not succeed in passing. The expenses of the committee, which it will ask the State society next year to reimburse, will not exceed \$75. The expenses of the previous Committee on Legislation, of which Dr. Sturgis was chairman, amounted to something over \$1,200, which sum the State society was called upon to pay, the amount being seven hundred dollars in excess of the sum that the society had authorized the committee to expend.

Respectfully yours,

HENRY G. PIFFARD,

Chairman Com. on Legislation Med. Soc. S. N. Y.

Proceedings of Societies.

NEW YORK ACADEMY OF MEDICINE.

Meeting of May 15, 1884.

The Vice-President, Dr. H. T. HANKS, in the chair.

PRACTICAL SUGGESTIONS UPON THE ALIMENTATION OF PATIENTS SUFFERING FROM DYSPHAGIA.—Dr. D. BRYSON DELAVAN read a paper the object of which was to direct attention to the morbid conditions with which dysphagia might be prominently associated, to point out its influence upon the course of such conditions, to discuss certain measures of relief not commonly made use of, and to urge the importance of resorting to such measures for their effect upon the disease, for the prolongation of life, and for the comfort of the patient. The causes of dysphagia were either organic or functional. Among the organic derangements which might lead to dysphagia be mentioned tuberculosis, cancer, syphilis, diphtheria, amygdalitis, and retropharyngeal abscess; among functional causes were spasm from any cause and paralysis. The general indications in treatment were: To secure rest, to avoid pain, to protect the parts from irritation, and to sustain nutrition. The means of administering nourishment were by the rectum and by the mouth, rectal alimentation being specially of service in cases in which, if food

could be carried to the stomach, the stomach nevertheless rebelled. But the chief point which the author wished to make related to the importance and manner of nourishment by means of a simple apparatus for conducting food into the stomach or beyond the point of obstruction in the pharynx or œsophagus. By this means the indications before mentioned would be at once fulfilled; rest would be secured, pain and injury avoided, and nutrition maintained. Dr. Delavan then described a very simple apparatus to be used as a stomach-pump. It consisted of a soda-water bottle, with a rubber cork containing two perforations, into one of which was introduced a small soft-rubber tube, and into the other another like tube, to which was attached the bulb of a Davidson syringe. Pressure upon the bulb would cause the liquid nutriment in the bottle to flow out of the first tube. On the end of this might be attached a suitable instrument for introduction through the stricture—as a No. 9 to a No. 13 catheter. If necessary to be introduced through the nose, a small-sized soft-rubber tube might be used. This apparatus was modeled after that of Dujardin-Beaumetz, but was much simpler and less expensive. The introduction of the catheter was much easier and less uncomfortable to the patient than the introduction of the ordinary stomach-tube, and, with a little experience, the instrument might be employed by the patient himself. Its introduction would be facilitated by dipping it into mucilage and having the patient swallow mucilage. The details of the use of the instrument and the importance of artificial alimentation in the various affections alluded to were considered.

Dr. JOHN C. PETERS said that in some of the acute affections referred to, as ordinary sore throat and diphtheria, it was not necessary to feed and stimulate the patient to the extent that some supposed. He sometimes thought we were going to the opposite extreme of the practice of physicians of olden times who starved their patients, and were now often over-stimulating and over-feeding.

Dr. R. C. BRANDEIS thought there would be some danger in intrusting the patient with the introduction of the tube. It would not always be convenient for the physician to be present as often as it was necessary to administer nourishment, and in those cases it might be found advantageous to leave the tube in permanently, or change it only occasionally. He could not say that he had often met with great difficulty in nourishing patients by the mouth in acute diseases. Concentrated nourishment, especially egg, was suitable to such cases.

Dr. GEORGE L. PEABODY referred to a proposed method which he had not yet had an opportunity to test practically.

Dr. W. C. JARVIS spoke of empty capsules, into which food might be introduced with a syringe and the puncture sealed. The capsules passed down more readily and with less discomfort than liquids.

Dr. DELAVAN closed the discussion.

CHANCER OF THE TONSIL.—Dr. R. W. TAYLOR read a paper on this subject. [See p. 577].

Dr. F. N. OTIS had never seen a case of chancre of the tonsil, but he knew of no reason why the lesion should not occur there as well as elsewhere, since it simply required the contagium and an open channel for infection. The course of the primary syphilitic lesion he thought must be very much the same wherever it occurred, certain allowance being made for the anatomy of the parts; and yet that course was more or less variable, even at the same locality, in different cases, and he thought the same would prove true regarding chancre of the tonsil. He did not think, therefore, that we should always expect to find the symptoms mentioned by Dr. Taylor, and, if we waited for their development in every case before making a diagnosis of chancre of the tonsil, we might fall into error:

For instance, he would not suppose that ulceration would always take place, for it often failed to develop in chancre elsewhere.

Dr. F. R. STURGIS had seen four cases of initial lesion of the tonsil, one being that referred to by the author of the paper as occurring in the boy in Bellevue Hospital. Two of the other patients were women, and the third a man. In all his cases, except one, the inflammatory symptoms had been well marked, and in the excepted case they were all of a subacute kind. Ulceration and enlargement of the tonsil had usually been well marked; deglutition had been difficult and painful. The principal difficulty in diagnosis would be to distinguish between an initial lesion and a gummatous infiltration of the tonsil, but in the latter condition there would not be the peculiar enlargement of the glands which characterized the initial lesion of the tonsil.

Dr. L. D. BULKLEY thought that one of the fortunate things about the paper was that it brought to public attention another possible source of syphilitic infection which otherwise might not be thought of. He then mentioned the case of an unmarried woman, thirty-two years of age, who suffered from difficulty with the tonsils, in which he was finally able to trace an initial lesion of that part to kissing, her betrothed having gumata of the mouth. The dire effects of syphilis had been shown in another instance where a man communicated chancre to the lips of one woman to whom he was paying his attentions, and before marriage courted another whom he inoculated on the tonsil. The man himself was now suffering from the late lesions of the affection in the kidneys.

Dr. JARVIS thought there was less liability to syphilitic infection by the mouth than was generally supposed, for the cavity was constantly bathed with saliva, and the virus had not much opportunity to enter the circulation before being washed away. Reference having been made to gummatous infiltration of the tonsil, he would take occasion to say that the enlargement of the gland from this cause could be diagnosed from ordinary hypertrophy by the fact that it was of a sclerotic nature, and great caution should be used in removing such a tonsil, as hemorrhage was much more likely to be severe than after an operation upon the hypertrophied gland. He had seen the mucous patch on the larynx, and inquired whether it was usually recognized.

Dr. TAYLOR was sorry that Dr. Otis had left before he had an opportunity to reply to his remarks. What *might* occur and what *did* occur were two quite different things in chancre of the tonsil. He had spoken of what had been seen, and not of symptoms which might or might not develop in a hypothetical case with theory for its basis. He did not think it of very much importance to the patient if the diagnosis was not made until toward the second stage. As regarded infiltration of the pharynx, we all recognized that; it might be unilateral or bilateral. As to the cleansing effect of saliva in preventing initial lesion in the mouth, it had not done it in the cases reported.

AMERICAN MEDICAL ASSOCIATION.

SECTION IN MEDICINE.

Dr. JOHN V. SHOEMAKER, of Philadelphia, Chairman.

(Concluded from page 565.)

Session of May 8, 1884.

THE TREATMENT OF DIABETES MELLITUS.—Dr. AUSTIN FLINT, Jr., of New York, read a paper in which he referred to the fact that sugar was occasionally found in the urine of persons apparently healthy. In his experience the proportion had been 1 in every 377 cases. He next called attention to the different

methods of testing for sugar, stating that, if Fehling's solution were used perfectly fresh, there could be no error in the result. He also commended Squibb's test. The specific gravity bore no relation to the proportion of sugar. Sugar might be present in urine of a low specific gravity. He had seen it in urine of a sp. gr. of 1.010. The quantity of urine need not be increased. He considered the liver to be a sugar-producing organ. In health this sugar was washed away by the blood as fast as it was formed. The sugar contained in the food was normally destroyed in the liver. In regard to prognosis, he said that, if the patient would submit to a certain course of treatment as soon as glycosuria was recognized, he thought that it was possible to effect a cure, or at least to remove the most characteristic symptoms, with the exception, perhaps, of the occasional temporary appearance of a small quantity of sugar in the urine. In the treatment, almost sole reliance should be placed on the use of a diet from which starches and sugar had been excluded. This should be carried out absolutely. Systematic daily muscular exercise should be enforced, but fatigue should be scrupulously avoided. All alcoholic excesses and the use of sweet fruits were to be avoided. In cases where the sugar persisted, the use of solution of arsenite of bromine, in doses of three drops three times a day, was often of service in diminishing the amount of sugar and relieving the distressing symptoms of the affection. This might be continued for weeks or months without unpleasant effects. The rigid diet should be continued for at least two months, even in the mildest cases. The return to ordinary diet should be gradual, and the urine should during this time be examined every five or six days.

THE MILK TREATMENT OF DISEASE.—A paper on this subject, by Dr. JAMES TYSON, was read by title.

BRIGHT'S DISEASE OF MALARIAL ORIGIN, by Dr. I. E. ATKINSON, of Maryland, was also read by title.

TUBERCULOSIS.—Dr. HENRY F. FORMAD, of Philadelphia, read a paper on this subject. He regretted having to speak in advance of the publication of the details of the experiments on which the paper was based. The points to which he intended to confine himself were: 1. The question of the contagiousness of pulmonary phthisis and of tuberculosis in general. 2. A brief definition of Koch's position on this question. 3. The objections to Koch's conclusions and to his interpretation of his experiments. The question of contagiousness was one of vast importance. If it were firmly established that tuberculosis was not contagious, the theory of its parasitic origin could not be sustained. He thought there was not the least proof that tuberculosis was ever conveyed by contagion. The apparent exceptions could almost always be explained. There was no analogy between the phenomena of tuberculosis and those of the contagious diseases. He then referred to tuberculosis from traumatism. In pleurisy or peritonitis, tuberculosis might develop if these affections became chronic. In such cases the bacillus was occasionally, if not frequently, absent. His objections were not to Koch's observations, for these he had gone over and confirmed, but to the interpretation that had been given of them. The proof of the etiological relation between the bacillus and tuberculosis was not complete. Again, it had been shown by competent observers that the bacillus was not present in all cases and in all products of tuberculosis, and, if present, that it was often in such small quantities as to have but little significance. As a rule, it was not present in the beginning of the disease. To prove that the bacillus was the cause of tuberculosis, it should be present in every case and in all the products of tuberculosis. It appeared to him that the bacillus was merely the concomitant of cheesy disintegrating material. Where the bacillus had not been found the effects had been attributed to spores. These could not be demonstrated. The miliary nodes

produced in the lungs in inhalation experiments had generally been supposed to be tubercular, but he thought they were more probably little foci of bronchial pneumonia. They could be brushed out with a camel's-hair brush, and the tuberculous lung be converted into a normal lung. Of course, if the matter were left in contact with the tissue for a certain length of time, they might be followed by tubercles, but he was referring to the rapid production of tubercles. It was not safe to reason from experiments on animals as to the effects which would be produced on man. Koch had himself fully recognized this point. The fungus which was poisonous to one animal might have no effect on another. The question was not whether or not the *Bacillus tuberculosus* would produce tuberculous, but whether other substances would not have the same effect. His experiments had shown that other substances would produce tuberculous. This condition had been produced by innocuous substances. Tuberculous could be produced without the presence of the bacillus. From his experiments he had come to the conclusion that neither the parasitic nature of tuberculous nor its contagiousness has been proved, and, further, that the bacillus of Koch was a valuable diagnostic sign of tubercular disease. Nothing had been proved by Koch's discovery as to the etiology of tubercle.

Dr. AUSTIN FLINT, Sr., thought that if tuberculous was an infectious disease, produced by a parasite, its contagiousness would follow as a matter of course. The presence of a parasite had been demonstrated. The great preponderance of evidence was in favor of the view that it was uniformly present in products recognized to be tuberculous. The bacillus was not found in products which from other characters were considered not to be tuberculous. The conclusion he had reached was that there was some essential connection between the presence of this parasite and the tuberculous disease. In regard to the contagiousness and inoculability of tuberculous, he thought that all testimony was in favor of them. Other causes might co-operate, and undoubtedly did co-operate, in the production of tubercle, but the presence of the specific parasite was essential.

Dr. WELCH agreed with Dr. Flint. Dr. FORMAD had spoken of tuberculous produced by inoculation of other substance than the bacillus. If bacilli were the sole cause, the condition could of course be produced in no other way. Koch, in his experiments, had adopted every precaution to prevent error. He had, with better methods of investigation, found the bacillus in every case. When the difficulties of the process required for the detection of the bacillus were considered, it was not at all wonderful that at times it should not be discovered. The essential point of Dr. Formad's question was whether or not tuberculous could be produced by other causes than the bacillus. The weight of evidence was in favor of the view that tuberculous could be produced by the inoculation of no other substance than the *Bacillus tuberculosus*.

The paper was further discussed by Dr. GEORGE M. STERNBERG, of the army, Dr. R. H. FRIZ, of Boston, Dr. TYSON, Dr. JANEWAY, Dr. CHARLES DENISON, of Colorado, Dr. W. T. BELFIELD, of Chicago, Dr. E. O. SHAKESPEARE, of Philadelphia, Dr. G. C. SMYTHE, of Indiana, Dr. H. C. EENST, of Massachusetts, Dr. PEPPER, and Dr. GREEN.

THE TREATMENT OF TYPHOID FEVER.—Dr. I. K. JACKSON, of Norfolk, Va., read a paper in which he contended that the discussion of this subject, though trite and hackneyed, could not be considered as finished until there was a better agreement among physicians as to the treatment of the disease, or until the mortality occasioned by it was much reduced. The object of the paper was to point out a line of treatment suggested by a recognition of some pathological conditions long since known to exist, but which had been ignored in looking for indications for

treatment. That these conditions had been overlooked was shown by the many and conflicting modes of treatment that had at different times been proposed, means not only not called for, but actually injurious. Some of these were enumerated to show that the pathology of the disease could never have suggested them. While all this conflict was being urged, the doctor declared that he had been pursuing one plan of treatment for thirty-five years, from which he had had no reason to deviate, and that it did not contain one of the long list of means to which he had previously referred, and which were generally employed in the treatment of this disease. He was reluctant to state the result of that treatment, but left each one to determine its value for himself. Among the first and most prominent pathological conditions which had attracted the attention of the author were the nitrogenous waste, the diminution of fibrin, the deficiency of urea and of all the nitrogenous excretions. The fact that they were not excreted was no proof that they were retained in the system, for, if they were, there would be signs of uræmic poisoning, which no one professed to have seen. They were not excreted, because there were none to be thrown off. One cause of this nitrogenous deficiency was the inability to digest nitrogenous food, owing to the absence of the digestive fluid, and this could not be secreted because of the congested and inflamed condition of the glands and glandular follicles whose duty it was to secrete these juices. Another possible if not probable cause was the consumption of nitrogen by the parasitic organism which was the acknowledged etiological factor in the production of enteric fever. That the parasite was a nitrogen-feeder was proved by the fact that it lived and thrived in nitrogenous matters, in urea and all nitrogenous excreta. Old logs, rotten wood, and leaf-mold, saturated with these excretions, had been known to be fruitful sources of this fever. If further proof were needed, it was found in the ammoniacal exhalation from a typhoid-fever patient, from his breath, his skin, and his urine. These exhalations were undoubtedly due to the decomposition of the nitrogenous constituents caused by this micro-organism.

This pathological condition furnished the most important indication in the treatment of the disease. As this nitrogenous waste could not be supplied by nitrogenous food, the author knew of no way of accomplishing the object but by the free administration of ammonia, even to saturation. Fortunately, this nitrogenous base furnished us with salts of such different therapeutical powers as to enable us to select any one suited to any stage of the disease and to any condition of the system. We had in the nitrate of that base the most sedative salt that we possessed, and in the carbonate the most stimulating salt of the materia medica. The nitrate of ammonium was capable of reducing the typhoid-fever heat down to 102° F., and of keeping it there. As this was not a dangerous degree, the patient was safe so long as it could be maintained. Ten or twelve grains of the salt every two hours were sufficient for this purpose. As the disease progressed and there was less need for a sedative, or if diarrhoea supervened, the acetate of ammonium was substituted for the nitrate, and acetate of lead and opium were administered at the same time. If nervous symptoms showed themselves, with a failure of the vital powers, the carbonate of ammonium, in combination with potassium chlorate, was resorted to; but, if coma developed, recourse was had to the hydrochlorate of ammonium, generally in five-grain doses, every two hours. The effect of this was magical. The doctor stated that he had never seen coma in a case which had been treated from the beginning with this ammoniacal course, and had only seen it in badly nursed cases, or in those treated by other means. He considered the delirium of typhoid fever to be due to deficient nourishment, a delirium of starvation. It never failed to

become quieted in a few hours after the free administration of ammonia. Wandering sometimes occurred, if the dose was too small or the intervals between were too long. Patients sometimes asked to have the interval shortened on account of a confusion of intellect which appeared when the dose had been postponed too long. For tympanites, turpentine was used, by enema or by the mouth. The pathological condition contended by some to exist in, and to be the cause of, coma was a thickened state of the envelopes of the blood corpuscles, on account of which the brain failed to be nourished, even though the blood contained the normal amount of nourishment. This condition suggested the hydrochlorate of ammonium as a solvent for the thickened envelope; but, whether this was its *modus operandi* or not, its effect was almost miraculous. Thus it would be seen that there was no stage of the disease in which one or other salt of ammonium was not used. Why should cold baths and cold affusions be used when the temperature could be reduced by simpler and safer means, and without the danger of reaction? The author had long since abandoned quinine as not being the proper germicide for the typhoid-fever parasite. It was, however, the antidote *par excellence* for the malarial poison, but, as the typhoid-fever-producing organism differed so essentially from that of malarial fever, it could not be expected that the same agent would destroy both. The parasite of malarial fever was a carbon-feeder, and that highly carbonaceous medicament, quinine, might be expected to be the best agent for destroying it, in accordance with the law (for which he had been contending), viz., that no organism could live in its own excreta, in the results of its life-processes. If carbonic-acid gas was thrown off as the excretory product of a life-process, a saturation with that gas would check the process and destroy the life. If alcohol was the result, then alcohol was the proper agent to destroy the organism causing it. If sulphureted hydrogen was evolved, then the compounds of sulphur were the most efficient means of checking the process. So, then, when ammonia was the excretory product, as in typhoid fever, ammonia, as had been shown, was the most efficient germicide. This furnished us with an additional reason for employing the salts of ammonium, for this nitrogenous base not only supplied the nitrogenous waste, but also destroyed the vitality of the organism which caused it. If this was a law, instead of accounting for the protection of the system against a second attack of contagious zymotic diseases by supposing that it was due to exhaustion of the pabulum necessary for the support of the parasite, why not attribute it to the infusion into the system of some excretory product which forever acted as a poison to the parasitic organism? This was the most probable explanation.

With regard to the periods of this fever: If it was recognized as early as the third day, it might subside at the end of the first week; but, if not recognized before the fourth or fifth day, it could not break before the end of the second week, but might at that time. If the treatment had not been inaugurated before the beginning of the second week, the fever could not be made to yield before the end of the third week. That it would yield then was almost an absolute certainty.

With regard to the diet, nothing was allowed but milk. Farinaeous preparations were never admissible. They could not be digested for want of the fluids containing diastase. There could not be any conversion of amylaceous food into dextrin or grape-sugar, so starchy food could not be assimilated. If administered, it underwent a fermentation which added to the gaseous distension and greatly complicated the case. Animal broths were never allowed until the later stages of the disease, or until there were signs of the secretion of the digestive fluids. In conclusion, the reader said: "The limited time allowed for this paper

has compelled merely an outline of a subject which deserves full discussion. It is left to the profession to test the value of the treatment which has been detailed."

THE SPECIFIC TREATMENT OF DIPHTHERIA AND CROUP.—DR. GEORGE A. LINN, of Monongahela, Pa., read a paper maintaining that corrosive chloride of mercury was a specific in diphtheria, when given in large doses in the early stage of the disease. The mere giving of a remedy did not necessarily constitute its use as a specific. Minute doses of quinine, given two or three times a day, would not be a specific in malarial disease; so in treating diphtheria with bichloride of mercury, the dose, time of giving, and stage of the disease, were conditions necessary to success. It should be given in large doses, one twentieth to one twelfth of a grain to a child, two or three years of age, and one twelfth to one eighth of a grain to an adult every three hours. It was best given in solution. The apothecary should make a solution in alcohol and dispense from this. The best vehicle was the elixir of pepsin, or elixir of pepsin and bismuth, in teaspoonful doses. In mild cases, the remedy should be continued to the end of the third day; in malignant cases, two or three days longer. If the treatment was begun in time, no tonic or sustaining measures were required. But, if the case was well advanced, brandy and iron should be added. If the membrane invaded the wind-pipe, causing croup, there was danger of suffocation from obstruction of the air-passage. This was due more to a spasmodic condition of the glottis than to the presence of membrane, and could be relieved by giving chloride of gold, which was a specific in simple croup. It acted like a charm, was tasteless, and caused no nausea. It should be given in solution in distilled water, the medicine being dropped into a glass and the use of a spoon avoided. The dose for a child two or three years old was from one fiftieth to one thirtieth of a grain every hour until relieved. In diphtheritic croup the bichloride of mercury was to be given in conjunction.

MUSCULAR HYPERTROPHY OF THE STOMACH.—DR. ALEXANDER MARCY, Jr., of Riverton, N. J., related a case of that very rare and interesting disease, occurring in his own practice. It was of pathological rather than of clinical interest. Its distinctive features, as marked at the autopsy, were described as follows: The stomach had undergone marked contraction, measuring in length only 12.5 cm. and in diameter but 3.75 cm. at the pyloric, and 4.35 cm. at the cardiac extremity. The lumen was greatly diminished, and the organ could not have held more than 60 c. c. of fluid. The little finger, pushed into the interior, encountered a stenosis at about the center of the organ, which it could scarcely pass. On opening the stomach, it was seen that this was produced by a narrow fibrous band, on either side of which was a stellate cicatrix. At the pyloric extremity the lumen was almost obliterated, and would scarcely have admitted a goose-quill. The mucous membrane was abnormally smooth, and the stomach-wall very much increased in thickness, measuring toward the pylorus 1.5 cm., and at the greater curvature 1 cm. This same thickening and narrowing had extended into the duodenum until it also involved the ductus communis choledochus, which was completely occluded. Beyond this the intestine rapidly assumed its normal dimensions. Under the microscope the following histological conditions were noted: The mucous membrane was very little altered, and in thickness was about normal. A slight growth of newly formed connective tissue was found among the glands. In the muscularis mucosæ there was a great increase in the amount of muscular fiber, which was mingled with many bundles of connective tissue. The increase of thickness in this coat was seven or eight fold, due almost entirely to the overgrowth of muscular fiber. The muscular element of the stomach was increased about three times in thickness. Here, too, this increase was due to an

hypertrophy of the muscular tissue, although in many places there was an intimate mingling with it of newly formed connective tissue. The fibrous tissue was slightly increased in thickness. The mucous layer was unaltered. The submucous layer had undergone the most peculiar change. In this there was not only found an irregular deposit of the same newly formed, imperfectly fibrillated connective tissue, such as was found elsewhere in the organ, but also an overgrowth of smooth muscular fiber. This fiber was scattered in larger or smaller bundles throughout the submucous layer, in some places exceeding the connective tissue in amount, in others falling short of it. Toward both the muscular wall and the muscularis mucosæ was the greater amount of muscular fiber, indicating, perhaps, that in its growth it had extended from these two tunics. The thickness of this coat was greatly increased, but to what extent could not be exactly determined, on account of the blending of this with the two contiguous tunics, produced by the deposition of newly formed muscular fiber in it. The lumen of the blood-vessels of the submucosa and the thickness of their walls were greater than in the normal stomach. The speaker added that this condition was not generally mentioned by writers on diseases of this organ, and that he believed its occurrence to be very rare. A case described by Thiergelder ("Atlas der pathol. Histol.," 1876, Tafel x, Fig. 1) resembled it somewhat, and Cornil and Ranvier, in their work on general pathology and morbid anatomy, referred to such a condition. It was very apt to be, and very often was, confounded with cirrhosis. There were no symptoms peculiar to this disease, and the treatment could only be palliative.

RETARDATION OF THE PULSE IN MITRAL INSUFFICIENCY. A paper by Dr. A. T. KEYT, of Ohio, was read by title.

THE ÆTIOLOGY OF ENTERIC FEVER, a paper by Dr. S. K. CRAWFORD, of Illinois, was read by title.

The following papers were then read by title: NEW THEORY AND NEW INSTRUMENT OF DIAGNOSIS, by Dr. L. G. AYRES, of Pennsylvania; THE ADVANTAGE OF THE USE OF MASSAGE IN RHEUMATIC GOUT, by Dr. DOUGLAS GRAHAM, of Massachusetts.

After a vote of thanks to the chairman and the secretary the section adjourned.

SECTION IN OBSTETRICS AND DISEASES OF WOMEN.

Dr. T. A. REAMY, of Cincinnati, Chairman.

Tuesday—First Day.

DESPERATE SURGERY AMONG WOMEN.—Dr. R. S. SUTTON, of Pittsburgh, Pa., read a paper entitled "Desperate Surgery among Women; the Proper Field for it; who should and who should not attempt it." The reader referred more particularly to laparotomy, which he thought should not be undertaken without special preparation and special conveniences, such as were offered by private hospitals for diseases of women.

Dr. McLEAN, of Troy, N. Y., Dr. DUNLAP, of Springfield, O., Dr. QUINBY, of New Jersey, and others took part in the discussion. Dr. Dunlap said that, theoretically, the advice given in the paper was proper, but, practically, it was difficult to carry it out.

The section then adjourned until afternoon, out of respect to the memory of Professor Samuel D. Gross, whose death was announced by the chairman.

THE EFFECTS OF TRACHELORRHAPHY.—In the afternoon session, Dr. JOSEPH TABER JOHNSON, of Washington, read a paper in which he considered the question whether the operation was advisable in all cases of laceration of the cervix, as some believed, or only in cases in which symptoms indicated it. The discussion which followed the reading of the paper brought out quite a diversity of opinion on this point.

Wednesday—Second Day.

Dr. THEOPHILUS PARVIN, of Pennsylvania, read a paper on PUERPERAL SEPTICÆMIA.

Dr. J. REEVES JACKSON, of Illinois, read a paper entitled A CONTRIBUTION TO THE RELATIONS OF OVULATION AND MENSTRUATION. The author maintained that there was absolutely no material relation between the ripening or bursting of the ovarian follicle, or ovulation, and the menstrual flow. The paper was discussed by Dr. BATTEY and others.

Dr. WILLIAM H. TAYLOR, of Ohio, read a paper on THE MANAGEMENT OF PROTRACTED LABOR.

Dr. HERBERT CLAIBORNE, of Virginia, read a paper on THE USE OF CHLOROFORM IN LABOR.

Dr. DUNLAP, of Ohio, presented A CLAMP FOR USE IN OVARY-TOMY AND HYSTERECTOMY.

NEW YORK PATHOLOGICAL SOCIETY.

Meeting of April 23, 1884.

GEORGE F. SHRADY, M. D., President, in the chair.

RUPTURE OF A DEGENERATED GLAND INTO THE TRACHEA; DEATH FROM ASPHYXIA.—Dr. W. P. NORTHRUP presented a specimen illustrating general tuberculosis with rupture of an enlarged bronchial gland into the trachea, obstruction of the right bronchus, and death from asphyxia five hours after the accident. The patient was two years and ten months old, an inmate of the New York Foundling Asylum. The child had always been delicate. The nurse stated that five hours before death it was taken with a fit of strangling and cyanosis. She also stated that she withdrew four long white worms from the mouth. When brought into the asylum the patient was moribund, and died within five hours from the attack, the symptoms being those of bronchial obstruction. At the autopsy, cheesy material, which was found to have entered from an enlarged gland through an erosion into the trachea, completely occluded the right bronchus. There were a few tubercular deposits in the other lung, but Dr. Northrup remarked that it was practically sound, and he could hardly understand why death should have taken place from asphyxia.

ENCYSTED EMPYEMA, DOUBLE BRONCHO-PNEUMONIA, AND PERICARDITIS.—Dr. NORTHRUP presented specimens illustrating these pathological conditions, all occurring in one patient.

TUBERCULAR PHthisIS AND TUBERCULAR MENINGITIS.—Dr. NORTHRUP also presented the brain and lungs of a child which had suffered from these affections, and also two lungs, from two different patients, the one the seat of pneumonia with tuberculosis and the other of simple diffuse broncho-pneumonia, and called attention to the fact that it was often almost or quite impossible to distinguish by the gross appearances between the two conditions. A microscopical examination was necessary to make a positive diagnosis.

Regarding the first specimen, Dr. W. M. CARPENTER remarked that the entire right lung becoming suddenly incapacitated from performing its duties was, in his opinion, quite sufficient to account for comparatively sudden death, and he was rather surprised that the child lived even five hours after the occurrence of the accident.

THROMBOSIS OF THE RIGHT VERTEBRAL ARTERY.—Dr. F. FERGUSON presented a specimen and narrated the following history: The patient was twenty-eight years of age, single, admitted to the hospital on the 2d of April. He had always been in good health, except that for five weeks before he had complained of earache and headache. About three weeks ago a slight discharge had taken place from the painful ear, and of

late the headache had been severer. He continued at his work until two days before admission, when he had a severe convulsion and afterward became drowsy; the face was expressionless, the pupils were normal, there was no paralysis, and the reflexes were exaggerated. Examination of the urine disclosed nothing. There was no apparent lesion of the abdominal or thoracic viscera. The patient died on the 20th of April, having had a temperature ranging up to 102°, the pulse varying from about normal to 120. During this time some convulsions occurred, and he lay in a comatose state. There was obstinate constipation. At the autopsy, a few small abscesses were found in one kidney, together with some congestion. The bladder was intensely congested, and there was an abscess of the prostate. The heart was practically normal. The organ of special interest was the brain, in which there was thrombosis of the right vertebral artery at the point of its blending with the left to form the basilar. By pressure upon the left vertebral artery, it cut off to a large extent the vascular supply through that channel. There was considerable blood-pigment in the neighborhood of the lesion, and also hæmorrhage into the lateral ventricle. There was no apparent brain softening.

LARGE MYO-FIBROMATA OF THE UTERUS.—Dr. FERGUSON related the history of the case and presented the specimens, which had been removed post mortem. The patient had been tapped several times for ascites, the accumulation of fluid within the peritoneal cavity having amounted altogether to 1,008 ounces.

VERTEBRÆ ILLUSTRATING THE RESULTS OF THE TREATMENT OF POTT'S DISEASE BY THE PLASTER-OF-PARIS JACKET.—Dr. L. A. SAYRE said the specimen of which he was about to give the history illustrated the excellent results of his method of treating spinal disease by suspension and the plaster-of-Paris jacket, as carried out, not by himself, but by two other physicians. The patient was a native of Ireland. Three years previously he began to suffer from Pott's disease involving several of the dorsal vertebrae, and for eighteen months he was paralyzed in the lower extremities and was unable to get out of bed. He was in several institutions in his native country, but received no benefit from treatment. Dr. L. H. Sayre and Dr. Hobart partially suspended the patient, applied a plaster-of-Paris jacket, whereupon he was immediately relieved, and within a week was able to get out of bed. He wore this jacket constantly for two years and a half, and when another was then applied, the old one was found not to have produced a single abrasion of the skin or to have given any discomfort. The spine was then completely consolidated, the patient was in good health, and up to about the time of his death performed efficient service as an orderly in several hospitals. He finally died from exposure and cold in one of the New York hospitals. A number of the dorsal vertebrae were found to have been involved in the disease, and the seventh, eighth, and ninth were completely fused into one solid mass.

Dr. CARPENTER referred to a case in which the patient at his suggestion consulted Dr. Sayre some years ago. A gentleman, aged fifty, had been a hump-back from his youth, and also had a stiff knee. While he was driving a team with a load of hay into a barn, the hump on his back came in contact with the upper portion of the door-frame, and sustained a severe injury—so severe that he was nearly unconscious—and from that time forward was scarcely able to do any work. Not long afterward he began to have impairment of movement in the lower extremities, which gradually increased, and finally paralysis of motion was complete, and continued so for nearly three years, being accompanied with extreme twitchings of the limbs, so violent that it became necessary to fasten them to the sides of his chair to prevent his being thrown out. At no time was there paralysis of either the bladder or the rectum. The appetite and gen-

eral condition remained good. He finally came to New York, where Dr. Sayre applied partial extension and then put on a plaster-of-Paris jacket. The patient was removed to his room, and on the following morning the paralysis of sensation in the lower extremities became complete. The jacket was immediately removed, and within ten hours sensation had returned. On leaving the city he carried away with him a knowledge of the principle upon which it was desirable for him to be treated, and constructed a set of pulleys by which he was enabled once or twice every day to straighten himself out. He also wore the plaster jacket as much as he could. After a while improvement began, and at the end of six months he was able to walk with the aid of crutches; at the end of a year and a half by the aid of a cane; and at the end of six years, the present time, he could walk as well as before the injury.

PHILADELPHIA CLINICAL SOCIETY.

Meeting of April 25, 1884.

The President, Dr. HENRY BEATES, JR., in the chair.

VESICO-VAGINAL FISTULA, WITH INVERTED BLADDER.—Dr. HANNAH T. CROASDALE reported a case which, she remarked, was perhaps of more than ordinary interest from two circumstances: first, from the enormous size of the opening in the septum, and, secondly, from the fact that from the orifice a bright round body protruded, which was discovered to be the bladder inverted. The patient, aged forty-seven, was admitted to the Woman's Hospital October 11, 1881. She had been married at the age of twenty-five, and had had one child stillborn. The labor was instrumental, and incontinence of urine occurred soon after it, thirty years ago. For this trouble she had never sought relief, and spoke only of her present suffering having begun one year before admission. This suffering had been so intense that she had been obliged to keep her bed for that length of time. The journey from her home had been made on a bed. Her appearance was deplorable. She had constant pain in the lower part of the abdomen, her bowels were constipated, her appetite was poor, and her face anxious, and she was constantly distressed lest the bed or her clothing should be moved and thereby her sufferings be increased. It seemed almost hopeless to expect to do anything for the poor woman's relief, so disturbed was her health from her desperate condition. Nausea and vomiting were almost constantly present. Her pulse on the day following that of her admission was 65, her temperature 99°, and her respiration 26. The quantity of urine passed in twenty-four hours could not be ascertained. The color was pale-yellow, the specific gravity 1.002, the reaction alkaline, and there was a trace of albumin.

After ineffectual attempts, she was finally etherized and thoroughly examined October 29th. The tumor, which was so exquisitely sensitive, was the inverted bladder, and the exposed mucous membrane was greatly inflamed and bled readily on being touched. The openings into both ureters could be distinctly seen. The mass was grasped, and, by gentle taxis, was reduced and retained by the slight support afforded by one of Skene's glass stylets, made to pass through the urethra with the distal extremity resting upon the upper edge of the fistulous opening. A vaginal glass plug was introduced into the vagina to aid in supporting the bladder. The inflamed condition of the parts forbade any further procedure at this time.

On the 30th of November she was again etherized and placed in the lithotomy position, and the edge of the fistula, which was about 5 cm. in diameter, was carefully pared and beveled from the vesical margin, giving a broad surface on the vaginal septum, and twelve sutures of silver were introduced. It was

necessary, before closing the fistula, to liberate adhesive bands at either angle, and then the margins of the opening were closed by the sutures and secured by perforated shot. A self-retaining catheter was introduced, to which was attached a piece of rubber tubing for conveying the urine to the urinal. The patient was then placed in bed, one sixth of a grain of sulphate of morphine was given hypodermically, and she was ordered lime-water and milk every two hours.

The following day there was much vesical tenesmus, which gradually subsided, and nothing especially worthy of note occurred until December 7th, when the sutures were removed. Union was not perfect at either angle, and in the center there was a small orifice which admitted the passage of urine.

January 6th the patient was again etherized; the edges of the three minute openings were freshened, and fine silver-wire sutures were introduced. The central and right openings promptly closed after this second operation, but the left, just at the site of the ureter, admitted the passage of a Snelling's probe. Three subsequent operations, done January 20th, February 3d, and March 28th, failed to close the minute opening. These attempts were always made with a probe carried through the urethra into the opening in the ureter, in order to prevent wounding or closing the latter.

It was now thought best to send the patient home and encourage her coming again in the autumn, as her stay had already been much prolonged beyond the usual time for keeping patients in the hospital, and she was discharged May 8, 1882, quite content on her part with the result of the many operations—six in all. After several months the urine ceased to pass through this opening, probably from the contraction of the cicatricial tissue.

The speaker added that she had not been able to find any record in literature of a bladder inverted through a vesicovaginal fistula.

G. BETTON MASSEY, M. D., *Reporting Secretary.*

Reports on the Progress of Medicine.

SKIN AND VENEREAL DISEASES.

By EDWARD BENNET BRONSON, M.D.

ZOSTER.—Why zoster should, as a rule with few exceptions, attack an individual but once, has always seemed like an insoluble problem. Dr. Paul Gerne ("Concours méd.," Feb. 2, 1884) seeks its solution in a supposed analogy between this disease and the eruptive fevers. He says that both develop, as a rule, but once in the same person; both are attended with prodromal symptoms, such as fever (the fever of zoster, he claims, is too often overlooked), loss of appetite, malaise, etc.; and both occur epidemically. This last point, however, with regard to zoster, is not absolutely decided, but the writer cites, in support of his position, an instance of zoster developing in a mother six days after attacking the infant she was nursing. He would consider zoster as a general constitutional disease with a local manifestation, of a nature similar to diphtheria, which is a general disease with local manifestations in the throat. He would explain the immunity from a second attack upon the same theory that would apply to other eruptive fevers. To those who object that an eruption so circumscribed as zoster, and unattended as it is by any serious general disturbance, could not impress the constitution profoundly enough to confer immunity from a second attack, he would call to mind the effect of vaccination, a mild disorder which manifests itself only at the point of

inoculation without any great constitutional disturbance, and yet protects in most cases against variola or revaccination.

Another contribution to our knowledge of zoster is made by Curschmann and Eisenlohr ("Deutsches Archiv f. klin. Med.," 1844, Bd. 34, Hft. 4), in a report concerning a case of zoster of the arm and forearm. The case was a severe one, arising without apparent cause. In the course of a month from the beginning of the attack a number of small nodules were felt in the affected district, evidently along the cutaneous branches of the axillary and other nerves. Many of these nodules were excised and microscopically examined. The process was found to be a *perineuritis acuta nodosa*, taking origin in blood-vessels of the nerve sheath and peri-neural connective tissue. The nerve substance itself was intact. The result of subsequent post-mortem examination was negative in regard to the spinal ganglia. The writers are disposed to believe that the part played by ganglionic affections in zoster is very much overestimated, and that alterations of the peripheral nerves themselves play a more important rôle in the disease than is generally attributed to them.

AINHUM.—It is singular that this malady of negroes, which consists only in what is apparently a spontaneous amputation of the little toes, should have thus far received no satisfactory explanation. The suspicion expressed by Dr. Duhring in his article on the subject ("Am. Jour. of the Med. Sci.," January, 1884), that the disease is artificially induced, is not a new one, but it is strange, if this be the explanation, that the method employed has never been detected. Occurring as the affection sometimes does in young children, and in individuals of widely separated countries, it is hardly reasonable to suppose that the same deception should be always repeated without a common motive relating to some specific object. It might have its origin in fetishism so common in the negro races, but, were this the case, the fact ought not to be so difficult to ascertain. On the other hand, it is equally difficult to assign the affection to any spontaneous pathological process. Stigmata have been explained as due to reflex action resulting from a profound religious impression upon the sensorium. But the sort of mental impression that could affect a negro's little toes is not easily imagined.

In Duhring's patient the disease had begun at the age of ten years, affecting the little toes of both feet, and the amputation was not complete till some twenty years later. It is stated that the father had lost both toes in a similar way, and that the mother was then suffering from the disease. One of the toes of the first patient was subjected to a microscopic examination, with the result of showing merely evidences of chronic inflammation. Dr. Wile, who conducted the examination, believed that the entire process was due to a disturbance of the circulation, and that the cause of the disturbance was intermittent in its action, "and probably to be found in the application and re-application of a ligature about the toe."

CHRYSAROBIN ADMINISTERED INTERNALLY.—It has long been suspected that the effect of chrysarobin used externally for psoriasis was largely due to absorption of the drug and to its action upon the general economy. The fact that when the remedy had been applied only to a limited portion of the surface the eruption was affected not only there but also over the entire body, was very good evidence of absorption. Most of the attempts, however, that have been made to accomplish the same result by giving the drug by the mouth have failed, owing to the disagreeable effects produced upon the *prima via* when given in such doses as were supposed necessary to efficiency. But a report upon the subject, recently published by Dr. Stocquart ("Annales de dermat. et de syph.," 1884, v), encourages further trial in this direction. This writer employed chrysarobin

bin internally in sixty-one cases of miscellaneous affections, out of which he claims fifty-six cures. The diseases were ecthyma, eczema, impetigo, lichen, pityriasis, prurigo, psoriasis, and urticaria. The dose was, at the beginning, one centigramme (one sixth grain) a day for infants, and three centigrammes for adults. These doses were well borne, and, when the case proved stubborn, the dose was increased. Sometimes the drug disagreed, the most frequent disturbance being in the stomach, and was attended with slight fever and vertigo. But the writer claims that such effects are unnecessary, and, when they occur, the drug should be discontinued for a while. He further reports a series of eleven cases in which the chrysarobin was administered hypodermically. In these cases the cures were effected more rapidly than when the drug was given by the mouth, but with the disadvantage of occasionally causing lancing pains and abscesses. The writer maintains that, when used internally, the remedy acts, by virtue of an elective action, upon the epidermis, the precise nature of which he does not pretend to define.

THE TREATMENT OF LUPUS.—The discovery of the tubercle bacillus in lupus has led Dr. J. Doutrelepoint to make trial of a new plan of treating the disease ("Monatshft. f. prakt. Dermatologie," 1884, iii, 1). He conceived the idea that, by applying a solution of corrosive sublimate directly to the ulcerating lupus surface, the bacilli might be rendered inactive and the disease process checked. His results were better than he anticipated. The strength of the solution he employed was one tenth of one per cent. The mode of application was by means of a many-folded compress ~~wring~~ out in the solution, which was applied to the affected part, covered with rubber tissue, and confined in its place by a bandage. Under this treatment fungous granulations became flatter, the secretion of pus was lessened, the ulcers healed over, the infiltrated, swollen, surrounding skin became paler and softer, and the tubercles, even where there was no ulceration, disappeared. The writer reports three illustrative cases.

RODENT ULCER AND ITS RELATIONS TO EPITHELIOMA.—Dr. G. H. Hume ("Brit. Med. Jour.," January 5, 1884) presents a study of three cases of rodent ulcer, in the course of which he takes issue with Dr. Thin, who has maintained that rodent ulcer originates in the sweat-glands. Dr. Hume says that the changes found in the sweat-glands are those of disintegration and not of morbid growth. In regard to the relation between rodent ulcer and epithelioma, he regards the former as a form of epithelioma which begins in the external root sheath of the follicles and in the sebaceous glands; of the same essential nature, therefore, as epithelioma, but differing from it pathologically in the mode of development of its cell growth, as it differs from it clinically in the absence of gland infection and in its slight general malignancy. These clinical differences, he maintains, may be found in the character of the cell growth in the two diseases. In epithelioma there is a marked tendency to an unrestrained cell-infiltration of surrounding tissues, so that infection of the lymphatic system readily occurs. The cell growth of rodent ulcer, on the other hand, is in the form of isolated masses, which, originating in the follicles and sebaceous glands, are, at least for some time, restrained by the firm fibrous sheaths of these structures. The tendency of these masses is to cause, by pressure on the tissues, a persistent ulceration in which they, as well as the tissues, perish. But because this local destruction takes place rapidly, and because of the absence of cell-wandering, lymphatic infection is not prone to occur.

MULTIPLE CUTANEOUS ULCERATION.—Dr. I. E. Atkinson ("Am. Jour. of the Med. Sci.," January, 1884) reports the following interesting case: The patient was a child twenty-eight months old. All poisoning from mercury, ergot, or other medication was excluded by the history. The symptoms were as follows: First papulation and vesiculation followed by a very

superficial destruction of the epidermic structures and most external dermal tissues. This was followed, more or less rapidly, by ulceration of a progressive character, destroying in a very short time muscles, fibrous tissue, cartilage, and even bone. The process was one of rapidly progressive molecular gangrene. The ulceration showed a tendency to affect similar parts of corresponding members and regions. The face and extremities were specially affected. There was no paralysis, but some bluntness of sensation. The child became greatly emaciated under the disease, and an obstinate diarrhoea set in; but finally the patient completely recovered, though with disfiguring scars. Dr. Atkinson believes this case to be allied to the "multiple caecothic gangrene" of Simon, regarding it as a form of trophoneurosis.

THE HYPODERMIC USE OF CALOMEL IN SYPHILIS.—This method of treating syphilis, which was first introduced by Professor Scarenzio, of Pavia, is described and warmly advocated by Dr. Julien in a recent article ("Annales de dermatologie et de syphilis," 1884, v). The method, though when first proposed it received considerable attention, has lately been almost entirely neglected, mainly on account of the troublesome abscesses which frequently resulted from it. Julien, however, maintains that, when properly used, it is superior in its effects to the treatment by injections of the bichloride. Ten to fifteen centigrammes of calomel are added to five centigrammes of gum arabic dissolved in one gramme of distilled water. Of this, ten centigrammes are injected at a time, by means of a Pravaz's syringe provided with a needle that should measure at least three centimetres. The backs of the arms and the buttocks are regarded as the best places to inject, and the injection should be made into the subcutaneous tissue rather than into the muscles. After the injection, the patient is required to remain quiet for several days. This treatment, it is claimed, is well borne by infants, the doses varying from three to six centigrammes, according to age. In most cases of adults, an aggregate of about forty centigrammes was sufficient to cause the disappearance of all manifestations of the disease; that is, four injections of ten centigrammes each. The usual procedure was to make two injections at one sitting—one in the right, the other in the left buttock, and three weeks later the same was repeated.

HEREDITARY SYPHILIS.—In a long and exhaustive article, Dr. M. Kassowitz ("Jahrbuch f. Kinderheilk.," 1884, xxi, Hft. 1 and 2) reasserts his former positions with regard to inherited syphilis. His main propositions are as follows: 1. The direct infection of the fetus from the father can be placed among the best constituted of scientific facts. 2. The few observations of the infection of the mother through a syphilitic fetus, the mother showing well-marked secondary symptoms, are not sufficiently clear or authentic to establish the occurrence of such infection upon a thoroughly scientific basis. 3. The theory that such infection of the mother exhibits itself through tertiary symptoms or syphilitic cachexia alone is not substantiated. 4. The syphilitic poison, in the great majority of cases of feti infected by the father, is arrested at the partition walls of the foetal and maternal circulations, and does not pass through, in spite of the active interchange of the nutritive fluids continued through many months. 5. That part of both organisms which constitute the partition walls in some way affords a high degree of immunity against syphilitic infection.

INJECTIONS OF HOT WATER FOR GONORRHOEA.—There is a law of limitations in therapeutics as well as in human happiness, according to which it is always possible to have too much of a good thing. Water is a good thing therapeutically, though one may drown in it. So is hot water; but Dr. Keyes has shown, none to soon, that it may do harm to the urethra. Quite a stir was made recently by an article in the "Medical Record"

recommending an abortive treatment of gonorrhœa by frequent injections of hot water. It seemed reasonable, and many tried it. Like all new remedies, it met with considerable success. In a disease of which at the start no one can say whether it will end as a *petite échauffement* in two or three days, or run a virulent course of six weeks or more, it is not strange if some good results should be recorded, and still less so when we consider that the mild or abortive urethritides greatly outnumber the cases of genuine virulent gonorrhœa. Keyes relates seven carefully observed cases in which the treatment was pursued, but with results decidedly discouraging to its enthusiastic advocates. In one case the effects produced were worse than indifferent (as in most of the cases)—indeed, were such as to characterize the method as a dangerous measure. The consequence in this case was severe cystitis with prostatitis, which confined the patient to his bed for many weeks. In two or three of the other cases the symptoms were distinctly aggravated by the injections. ("Jour. of Cutan. and Ven. Dis.," March, 1884.)

TUBERCULAR PERI-URETHRITIS.—Dr. Englisch ("Med. Jahrbuch," 1883, Hft. 3 and 4) has been led by experience to believe that all diseases of the urinary and sexual organs in tuberculous subjects run a course peculiar to themselves. He believes that peri-urethritis occurring in those who are tuberculous differs from the same as occurring in non-tuberculous subjects sufficiently to warrant the above title. It may arise from the same causes as does the ordinary form, but is rarely traumatic. The disease generally takes its origin in an inflammation of the urethra proper. But a urethral discharge in these individuals is more apt to be the expression of the tuberculous diathesis than of an infection from a gonorrhœa. Such cases of urethritis are distinguished by their chronicity and by their mild character. After the discharge has lasted a long time, a swelling is developed in the perineum, which may remain unaltered for a long time, till at last it breaks. The skin over the swelling is not reddened, the subcutaneous tissues are not infiltrated nor hard, and the swelling is never tender. The border is well defined and developing on one side; it does not tend to go beyond the median line. It increases in size slowly, and may occasion some difficulty in urination. Generally it is unaccompanied by fever. When ulceration does not occur, the tumor will slowly undergo absorption, perhaps lasting for years. If it should break down, the rim of the opening is thin, but the walls of the abscess are found to increase in thickness rapidly toward the circumference. The pus discharged is small in amount and thin. The abscess is generally very slow in healing, and constitutional measures are always necessary to assist the local treatment.

Miscellany.

THERAPEUTICAL NOTES.—*Aluminium in the Treatment of Phthisis.*—The "Lancet" quotes from an article in the "Pharmaceutical Journal" in which Dr. Pick affirms that aluminium and its compounds constitute most effective remedies against pulmonary tuberculosis, as shown by experiments on rabbits and by clinical observations. In one case, where infiltration of the apices of the lungs had occurred, removal of the lesion and a disappearance of all the symptoms are said to have followed the administration of the metal in the following form:

Metallic aluminium.....	80 grammes;
hydrate of aluminium.....	50 "
carbonate of calcium.....	50 "
gum tragacanth.....	4 s.

Divide into sixty pills. One to be taken three times a day.

The Bromides in the Treatment of a Neurotic Diarrhœa of Children.—At a recent meeting of the Harveian Society, of London, a report of which we find in the "Medical Times," of London, Dr. Lees called attention to a class of cases, not very uncommon in children, in which the main symptom was an irresistible impulse to defecation, experienced almost immediately after taking food. Colic pain might or might not be present, but there was no sensation of weight at epigastrium, heart-burn, flatulence, or other symptom of dyspepsia. The motions were usually semi-solid, not often watery or slimy, and frequently contained undigested food. Usually a motion was passed almost immediately after every meal, and perhaps once or twice more during the twenty-four hours. Dr. Lees pointed out that these symptoms were evidently due to a hyper-peristalsis of the alimentary canal, without increase of secretion, the two factors of ordinary diarrhœa being here disassociated. Such increase of peristalsis was probably due to irritation of the vagus nerve, which supplies the excitator fibers to the intestine, the splanchnics conveying the inhibitory fibers. The proximity of the nucleus of the vagus to that of the trigemini, in the medulla, indicated the possibility that this increased excitability of the intestine might in part be due to dental irritation, the cases in question usually occurring during the period of the second dentition. Believing in the purely neurotic origin of the symptoms, Dr. Lees had treated several cases with bromide of potassium simply, without opium or any astringent, and had obtained immediate success, even in cases which had persisted for several months. The diarrhœa was usually arrested in a few days, and occasionally the children became so costive that the medicine had to be discontinued. Four cases were narrated, also a similar case occurring in an adult, in all of which speedy relief was given by the bromide. In conclusion it was remarked that individuals who suffered from these symptoms were often of a markedly neurotic temperament, timid, and easily frightened.

Benzoate of Sodium in the Summer Diarrhœa of Infants.—The "Bulletin général de thérapeutique" quotes from the "Gazzetta degli Ospitali" a summary of an article, by Dr. R. Guaita, that originally appeared in the "Rivista Italiana di Terapia ed Igiene," in which the summer diarrhœa of infants is considered as a zymotic disease produced by a special microbion introduced from without or developed during intestinal digestion, dietetic errors, defective hygiene, and excessive heat being the predisposing causes. On this theory, Kapusinsky and Zilewicz employed benzoate of sodium for the vomiting and diarrhœa of infants, but in conjunction with subnitrate of bismuth. Guaita has made use of the benzoate alone in fifty-three cases of children between six months and two years of age, in thirty-five of which the affection had lasted from twenty-four to thirty hours, and in the eighteen others from six to fourteen days. In the first category, a cure resulted in every instance within forty-eight hours; in the second, after an average period of twenty-one days. Not a single death occurred. After a purgative (calomel or jalap), the author gives from four to six grammes of the benzoate, in one hundred grammes of water, in the course of twenty-four hours, and continues the treatment for two days. On the third day, a gentle purgative is given (magnesia or manna), and the use of the benzoate is resumed. At the end of two days more, improvement in the passages is constantly observed—they are no longer fetid, and the vomiting ceases. During the treatment, the diet is strictly regulated, and the child drinks nothing but lemonade and a few teaspoonfuls of wine; milk and broths are absolutely proscribed, but nurslings are given the breast not more than four times in the twenty-four hours. Other drugs may be given to meet special indications.

Naphthalin as a Remedy for Diarrhœa.—At the recent meeting of the German Kongress für innere Medizin ("Deutsche Medizinische Zeitung," April 28, 1884), Dr. Rossbach, of Jena, reviewed the usual indications followed in the treatment of diarrhœa, dividing the drugs employed into four groups: calomel and castor-oil to get rid of irritating and decomposing fecal masses; opium to allay exaggerated peristalsis; astringents to diminish the swelling of the mucous membrane and give consistence to the feces; and alkaline waters to stimulate the portal circulation. In view of the conversion of calomel into corrosive sublimate in the intestinal canal, attention had lately been directed to the probability that the drug acted by virtue of the antiseptic properties of

the latter substance, but it was impracticable to introduce enough of it to make sure of the result without the danger of poisoning the system. Naphthalin, he remarked, possessed the same antiseptic property, while it could be given in doses of five grammes a day, for weeks together, without any bad effect—indeed, in those amounts, it increased the appetite in many instances. He had found it of benefit in inveterate cases of catarrh of both the small and the large intestine, with and without ulceration, provided there were no incurable organic disease, like carcinoma, at the bottom of the trouble. He had not tried it in the diarrhoea of tuberculosis or in that of typhoid fever. The usual daily dose was five centigrammes. The disagreeable odor of the drug could be overcome by a little oil of bergamot.

THE COLLEGE OF PHYSICIANS AND SURGEONS.—The following is a list of the honor-men at the recent commencement: J. H. Bradshaw, of New Jersey; A. Brothers, S.B., of New York; B. B. Gallaudet, A.B., of New York; L. W. Hotchkiss, A.B., of New York; G. S. Huntington, A.B., of Connecticut; G. R. Lockwood, Jr., A.B., of New York; E. K. Morton, of New Jersey; A. B. Pope, of Georgia; H. J. Schiff, of New York; and J. C. Stewart, B.S., of New York. The Harsen prizes were awarded as follows: The first, of \$150, to G. S. Huntington, A.B., of Connecticut; the second, of \$75, to L. S. Manson, of New York; the third, of \$25, to G. W. Weld, D.D.S., of New York. The first prize for proficiency at examination, \$500, was awarded to G. S. Huntington, A.B., of Connecticut; the second, \$300, to G. R. Lockwood, Jr., A.B., of New York; the third, \$200, to E. K. Morton, of New Jersey. The alumni prize of \$500, which, as we stated last week, was awarded to Dr. M. Allen Starr, was for an essay entitled "The Central Nervous System."

THE MEDICAL COLLEGE OF VIRGINIA.—The Board of Visitors announce that they will hold an adjourned meeting in the college building on Friday, June 6th, to elect professors of obstetrics, practice of medicine, anatomy, and materia medica and therapeutics.

THE NEW YORK CANCER HOSPITAL.—At the ceremony of laying the corner-stone of the hospital building, Dr. W. H. Draper delivered an address. The board of consulting physicians consists of Dr. Fordyce Barker, Dr. T. Gaillard Thomas, Dr. John T. Metcalfe, Dr. Thomas M. Mackoe, and Dr. Thomas Addis Emmet. In the list of trustees we notice the names of Dr. William T. Bull, Dr. Clement Cleveland, Dr. James B. Hunter, Dr. Francis P. Kinnicut, and Dr. George L. Peabody.

THE SECTION IN STATE MEDICINE OF THE AMERICAN MEDICAL ASSOCIATION.—Dr. Deering J. Roberts, of Nashville, Tenn., the chairman of the section, informs us that, at the recent meeting of the association, it was he that brought up the resolutions urging Congress to provide for the Museum of Hygiene, and likewise Dr. Pratt's resolutions relating to defective immigrants, and that he did not move to table the latter, as was stated in our report of the meeting, in which, we regret to observe, Dr. Roberts was spoken of as "Dr. Robertson" and as "Dr. Robinson." Dr. Roberts also wishes it understood that he seconded Dr. von Klein's resolutions relating to medical education. In his address as chairman of the section, Dr. Roberts first considered the subject of medical education, and took the ground that it was not a matter for legislative control, through State boards of health or otherwise, and that, if medical education, or the profession, was to be elevated, advanced, or regulated, in the American Medical Association alone could it be accomplished. He advocated the establishment of a Department of Health, with a chief a member of the President's Cabinet, recommended by him and confirmed by the Senate, with the position and powers of the other cabinet officers. He attributed the failure of the National Board of Health to enlist the confidence which it required, and which the subject deserved, to the defective and cumbersome form of its organization, and expressed the opinion that, if it had been constituted like the other departments of the Government, it would have had a vigorous life.

JÜRGENSEN ON PNEUMONIA.—The "Lancet" thus condenses a report of Jürgensen's remarks, made in a debate on pneumonia at the German Medical Congress, from the "Berliner klinische Wochenschrift":

"Dr. Jürgensen (Tübingen) opened a debate upon genuine pneumo-

nia, remarking that not long since it was thought that the study of pneumonia was closed. It was considered as established that its cause was exposure to cold, its nature a local inflammation, its issue a crisis, and its treatment antiphlogosis, especially venesection. Laennec and Skoda by their research in physical examination, Rokitsansky by his anatomical studies, and Dietl in his opposition to venesection, led the way in a conversion of opinion. Gradually another conception of the disease arose—viz., that in croupous pneumonia we had to do not with a local but with a general disease, which is mainly, but not solely, localized in the lungs. This conception must now be further extended to the admission that it is an infective disease. Ten years ago it was difficult to establish this; but modern experimental pathology has come to its support, so that the old contention of cold being the sole cause of pneumonia bids fair to disappear, and Dr. Jürgensen did not believe that more than four per cent. of the cases could now be assigned to this cause. It has also been shown, contrary to former notions, that the weakly are more liable to be attacked than the strong; that most cases occur between the ages of one and fourteen, and that those above the age of forty-five are twice as numerous as those between fourteen and forty-four years. As to atmospheric influences, it had been proved, at least in Tübingen, that scanty rainfall increases and heavy rains hinder the development of the disease. From his experience he had traced a parallelism between pneumonia and enteric fever as regards their relation to the humidity of the soil. A further analogy between these diseases is to be found in the influence exerted on them by insanitary dwellings. He referred to Emmerich's discovery at Munich of the pneumonia micrococcus beneath the floors of a barrack, where the disease had much prevailed, and considered that much light had been cast in this direction on the pathogeny of the disease, as well as on its treatment. Whether pneumonia was contagious could not be stated with certainty. Dr. Flint was disposed to think so; but in so widely spread a disease more direct evidence of its transference was required, since cases of supposed contagion might be referred to exposure to similar insanitary surroundings. Was the pneumonic virus single or multiple? The answer to this question might be found in the study of the 'pneumonia coccus' and the results of its inoculation in animals. Clinically, the unity of the disease would seem to be established, and the occurrence of a typical case was not opposed to this any more than it was in the case of the specific fevers. It seemed likely that the virus circulates in the blood, and is especially prone to settle in the lungs and pleura; but under certain conditions it may manifest itself in other regions also. Nauwerck (Tübingen) had found in thirteen cases of pneumonia the 'cocci' of Friedländer in the kidneys, and Jürgensen, in one case marked by cerebral symptoms, found them in the brain. Clinically he would group all cases into those (1) of general infection, (2) with cardiac lesion, and (3) with pulmonary lesion predominating, although in the last instance the heart always suffers. Treatment then should be prophylactic, especially in improving the sanitary condition of the dwelling. Iodine had been strongly recommended as aborting the disease, but Jürgensen was not able to confirm this. Beyond such attempts to arrest the disease at its onset, treatment must be symptomatic; and numerous views were held as to the most appropriate means, all recognizing the importance of maintaining the force of the heart. Antipyretic measures were the best, for they also fulfilled this latter condition. In conclusion, he summed up his thesis as follows: 1. Cold is rarely an exciting cause of pulmonary inflammation. 2. Strong individuals are less frequently attacked than the weakly. 3. Antiphlogosis in the old sense must be rejected."

A HYDROPHOBIA STORY SPOILED.—A somewhat harrowing story has been going the rounds of the British journals of a man's having been bitten by a panther in India, and having died of hydrophobia after his return to England, with the usual accessory of "barking." The man's medical attendant now writes to the "Lancet," however, that the injury, which was an ugly one, consisting of a fracture of the radius and a number of lacerated wounds, had been wholly recovered from, save a stiffness of the elbow, and that the poor fellow was considering whether or not he should enter a London hospital, for the purpose of having the adhesions broken up, when he contracted a pneumonia, in the course of which he became delirious and died.

Original Communications.

THE ARCHITECTURE OF THE SPINAL CORD, AND ITS RELATIONS TO MEDICINE.

By AMBROSE L. RANNEY, M. D.,

PROFESSOR OF APPLIED ANATOMY IN THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL.

(Continued from page 353.)

THE BLOOD-VESSELS OF THE CORD.

The tissue of the spinal cord is peculiarly rich in blood-vessels. The arteries enter from the pia mater and accompany the processes which that membrane sends into the substance of the cord. They subdivide after entering the cord and form a net-work of capillaries both in the gray and white substance. Since the vertebral arteries give off branches that form the anterior and posterior spinal arteries which run continuously from the foramen magnum to the conus terminalis, and since the intercostal and lumbar arteries anastomose freely with the anterior and posterior spinal vessels, *counter-irritation over the spines of the vertebrae* causes a direct effect upon the vascular supply of the cord itself as well as upon the meninges.

The intercostal and lumbar arteries enter the vertebral canal, by means of the intervertebral foramina, in company with the nerve-roots.

The capillaries of the cord empty into two venous trunks that run in the gray commissure of the cord on either side of the central canal for its entire length (Fig. 5), and also into a large vein that accompanies the anterior spinal artery for the entire length of the cord, lying in the anterior median fissure. In the posterior median fissure a similar vein may be traced for the entire length of the cord, although it increases in size from the upper to the lower spinal segments. The veins within the spinal gray matter anastomose with the external veins already described by horizontal branches; and these, again, join with each other, and also with the large venous plexuses that lie in the fatty tissue outside of the dura and with the external vertebral veins.

THE VERTEBRÆ AS GUIDES TO THE SPINAL SEGMENTS.

By sharp friction over the spinal column, the tips of the spinous processes can be made very apparent as well-defined red spots. They can then be readily counted.

It is desirable often to know what part of the vertebral column corresponds to the level of origin of each pair of spinal nerves. The spines of the vertebrae can be felt even in fat subjects, and thus guides may be had in each individual to locate the levels of the various spinal segments. To do this with accuracy, however, is rendered somewhat difficult (1) by the fact that the spinal nerves do not escape from the foramina between the pedicles of the vertebrae at the same level at which they arise from the spinal cord, and (2) because the tips of the spinous processes do not correspond to the bodies of the corresponding vertebrae in all parts of the spinal column.

The spinal nerves escape from the cervical foramina nearly on a level with their origin from the cord, but the obliquity of the nerves increases steadily in the dorsal and lumbar regions, so that the lowest nerves that constitute the cauda equina have a very long course before they escape from the foramina of the lumbar region and the sacrum.

Gowers gives the following deductions as aids to determine the situation of the bodies of the vertebrae during life: "The tips of the cervical spines correspond nearly to the lower borders of the corresponding vertebrae. Each of the three upper dorsal spines corresponds nearly to the upper border of the body of the vertebra below. From the fourth to the eighth dorsal, each spine corresponds to the middle of the vertebra below. The ninth, tenth, and eleventh spines slope less, and their tips again correspond to the upper borders of the next vertebrae, while the rest of the spines are opposite the bodies of their own vertebrae." Fig. 7 will make these statements apparent.

With these guides to the bodies of the vertebrae, it now becomes necessary to consider the relations of the spines to the origins of the spinal nerves. In the cervical region, the first three spines correspond to the origins of the third, fourth, and fifth cervical nerves; the sixth cervical spine corresponds to the origin of the eighth cervical nerve, and the intervals between the fourth and fifth spines, and the fifth and sixth, correspond to the origins of the sixth and seventh cervical nerves respectively.

In the dorsal region, the seventh cervical spine usually corresponds to the origin of the first dorsal nerve; the first dorsal spine to the third dorsal nerve; the second spine to the fourth nerve; the third spine to the fifth nerve; the fourth spine to the sixth nerve; and so on down to the tenth spine, which lies opposite the twelfth nerve. It may therefore be given as a rule that *the dorsal spines lie opposite the level of the origin of the nerve that escapes from the spinal canal two vertebrae lower down.*

The lumbar and sacral nerves all arise within a space that corresponds to the interval between the eleventh dorsal spine and the first lumbar spine. The course of each nerve within the spinal canal from the first lumbar to the coccygeal nerves, therefore, becomes longer than the preceding ones as they are given off from the cord.

The excellent cut devised by Gowers, which is here introduced, will enable the reader to more easily follow the preceding text. It shows in a diagrammatic way the varying relations between the bodies of the vertebrae, the origins of spinal nerves, and the tips of the vertebral spines. It must be always remembered that the spinal nerves are named from the *situation of the foramen* through which they escape from the canal of the vertebral column, and that the name of the nerve must never be construed as indicating the level of its point of origin. Thus, for example, the sacral nerves escape into the cavity of the pelvis, but they arise in the lumbar region. If we seek to locate spinal lesions that tend to create symptoms referable to special nerves, we must first know the *level of origin* of the nerves that exhibit evidences of impairment, as a result of the spinal lesion. The cut of

FIG. 7.—A DIAGRAM DESIGNED TO SHOW THE RELATIONS OF THE VERTEBRE TO THE SPINAL SEGMENTS, AND OF THE SPINAL NERVES TO THE MOTOR, SENSORY, AND REFLEX FUNCTIONS OF THE SPINAL CORD (GOWERS).

Gowers (Fig. 7) will also make the distribution of the spinal nerves apparent.

THE MINUTE STRUCTURE OF THE CORD.

The nerve fibers, nerve cells, and connective tissue of the cord have been already referred to in a general way, but a few histological statements respecting them will not be out of place.

THE NERVE FIBERS.—Schwann's sheath has not yet been satisfactorily demonstrated as investing any of the fibers of the cord, and it may be said that, as far as our present knowledge goes, all are destitute of it. Both medullated and non-medullated fibers exist in the cord. The former are found in great abundance in the white substance and the white commissure, and also in the gray matter; the latter are not detected in the white matter or the white com-

missure. The medullated fibers vary in size. In the anterior columns they are very large; in the columns of Goll they are much smaller; in the gray matter they are still finer. The axis-cylinder, as well as the medullary sheath of the fiber, may be discerned in cross-sections of all.

The non-medullary fibers of the cord appear as naked axis-cylinders, without any medullary sheath. They exist only in the gray substance, and form a fine and close network of fibers, in which ganglion cells are imbedded. The fine medullated fibers of the gray matter form, however, the preponderant element.

In the so-called white substance of the cord three varieties of fibers may be demonstrated:

1. The *longitudinal strands* or bundles, which constitute the bulk of the conducting tracts to and from the brain or between the different spinal segments.

2. The *oblique fibers*, that are interlaced with those of the preceding set, and are relatively few in number. These are probably fibers of termination of the posterior nerve roots.

The column of Burdach is traversed by many of the bundles of fibers derived from the posterior nerve roots.

3. The *horizontal fibers*, that are chiefly detected in the white commissure and in the region of the anterior nerve roots.

THE GANGLION CELLS.—These are the most striking feature of the gray matter. They vary (1) in size, according to their situation, and (2) in the presence or absence of the peculiar process known as the "axis-cylinder process," which differs from the others in being unbranched, and in tending to increase in size as it departs from the body of the cell. They have no cell-membrane; their nucleus is large; a glistening nucleolus exists; and pigment granules are usually present in abundance in the protoplasmic mass. Some cells, that are destitute of the so-called "axis-cylinder process," unite with the nerve fibers, according to Gerlach, by means of a fine network of nerves.

The cells of the anterior horns are the largest, and have many processes; those of the vesicular column of Clarke are next in point of size, and nearly round; and those of the posterior horns are the smallest, and are spindle-shaped. The well-defined groups, which are characteristic of the anterior horns, are not found in the posterior horns. Some attractive theories have been advanced respecting the individual functions of the various forms of cells found within the cord. The motor function of the large cells of the anterior horns seems to be well established; but that a special form of cell may be designated as sensory, another as vaso-

motor in function, and a third as trophic, seems improbable and visionary.

A middle horn of gray matter is described by some authors as arising from the external portion of the gray mass between the two horns commonly described. It is also called the "intermediary lateral tract." In close relation to this tract the reticular processes (process of Lenhossek) is discerned. It consists of a matrix of neuroglia and an interrupting net-work of fibers.

Ross describes a collection of cells in the cervical region that develop their processes after birth (in which respect they differ from other groups) and which are of large size. He draws the inference, from their situation and late development, that they are chiefly concerned in the complex movements of the hand and fingers, or of the corresponding fore-limbs of animals.

The *gray matter of the cord* differs from that of the brain in respect to its distribution, as it is confined exclusively to its central portion. In the brain the larger proportion of gray matter is distributed upon its exterior (cerebral and cerebellar cortex).

THE NEUROGLIA.—A basement substance of connective-tissue elements is found within the cord, in the meshes of which the nerve cells, the nerve fibers, and the vessels are enveloped. It serves to give support to these structures and firmness to the cord as a whole. It springs from the pia mater, by numerous septa that enter the cord and form channels for the blood-vessels. These septa divide and subdivide to form the delicate net-work in which the nervous elements are imbedded. The researches of Boll appear to show that the chief histological element of the neuroglia is a multipolar connective-tissue cell, whose processes are unbranched. They are often described as the "spider-cells" of Jastrowitz, and as Deiter's cells. Their nuclei correspond to what Henle described as "granules" of the cord. These cells are found abundantly in the white matter, especially in pathological specimens. The neuroglia is probably the chief factor in the formation of the so-called "gelatinous substance" of the gray matter (Fig. 5).

The regions of the cord in which the neuroglia is most apparent are proportionately destitute of nerve cells. These regions include (1) the periphery of the cord; (2) the borders of the fissures; (3) the circumferential area around the central canal, and to the mesial side of the head of the posterior horns (the *substantia gelatinosa*).

The preponderance of connective tissue in the posterior horns, in contrast to that of the anterior horns, helps us to interpret the frequent occurrence of inflammatory affections in the posterior portions of the cord.

The *substantia gelatinosa* is darker in color than the rest of the connective-tissue formation of the cord. For this reason it was formerly classed as a part of the gray substance. In the cervical and dorsal regions of the cord it presents an oval outline in all cross-sections, but in the lumbar region it becomes more circular. The tubercle of Rolando may be considered as an extension of this column upward into the substance of the medulla.

APPEARANCE OF A TRANSVERSE SECTION OF THE SPINAL CORD.

The arrangement of the gray and white substance of the spinal cord is seen only on a transverse section. In order to properly appreciate the special points in the construction of these two portions, several transverse sections must be made at different heights in the cord, since the relative proportion of the gray and white substance differs in the cervical, dorsal, and lumbar regions. The regions usually selected for these transverse sections are the upper cervical portion, the center of the cervical enlargement, the center of the dorsal region, the lumbar enlargement, and the terminal portion of the cord. In the cervical region the white substance is the most abundant. In the dorsal region the gray matter is relatively smaller than at any other point. In the lumbar enlargement the gray matter is the most extensively developed.

When we view the appearance of the spinal cord on transverse section, we perceive that the gray matter is arranged in the same general way in all of its segments. This has been compared to the capital letter "H," because its two lateral halves are connected together by a transverse band, "the transverse commissure of the gray substance." Each lateral half of the gray substance is *crescentic* in form, presenting an anterior and a posterior projection, termed the *anterior* and *posterior horns*. The former of these is broad and blunted, and does not reach the surface of the cord. The latter is thinner and more pointed, and approaches the exterior surface of the cord near the point of attachment of the posterior roots of the spinal nerves.

The *anterior horns* are much larger than the posterior in the cervical region, but less so in the dorsal and lumbar. They contain the so-called "motor-cells."

The *posterior horns* are also studded with nerve-cells, but they are smaller and more spindle-shaped than the motor cells. The posterior horns are very large in the lumbar enlargement of the cord (see Figs. 8 and 13).

The *motor cells* are commonly multipolar. One of these poles is slender and unbranched, and tends to increase in size as it passes from the body of the cell. It is known as the "*axis-cylinder process*" (Deiter's). In favorable sections of the cord it can be traced into the anterior root of a spinal nerve. It probably becomes continuous with the axis-cylinder of a motor nerve-fiber. The other poles of the cell divide into branches as soon as they leave the body of the cell and terminate in a delicate net-work of nerve-fibrils (network of Gerlach) which exists in the spinal gray matter. The motor cells are distributed in well-defined groups, whose situation changes somewhat in different regions of the cord. These are shown in the admirable drawings of Gerlach and Erb (Figs. 5 and 8).

The admirable diagram of Erb (Fig. 8) illustrates the differences in shape of the horns of the spinal gray matter in the cervical and lumbar regions of the cord, and also the arrangement of the motor cells of the anterior horns into groups that are specially named. It will be seen by reference to the diagram that the so-called "median," "antero-lateral," and "postero-lateral" groups of cells change their relations to each other at different levels of the cord.

FIG. 8.—SEMI-DIAGRAMMATIC TRANSVERSE SECTION OF THE GRAY SUBSTANCE OF THE CERVICAL (A) AND LUMBAR ENLARGEMENTS (B) OF THE SPINAL CORD. (Erb.)

A. *a*, median group of cells; *b*, antero-lateral group; *c*, postero-lateral group; *d*, vesicular column of Clarke. B. *a*, median group; *a'*, group that appears first in the lumbar region, possibly belonging to *a*; *b*, antero-lateral group; *c*, postero-lateral group. Note that the cells are few and scattered in the posterior horns, and also that the shape of both horns differs markedly in A and B.

Their relative size also varies at different levels. It will be again observed that the vesicular column (*column of Clarke*) is very well defined in the cervical region and is wanting in the lumbar region.

FIG. 9.—A PIECE OF THE WHITE SUBSTANCE OF THE SPINAL CORD, AS SEEN ON TRANSVERSE SECTION HIGHLY MAGNIFIED. (Erb.)

Note that the nerve-fibers cut across present their axis-cylinders toward the plane of the section, and that Deiter's cells are apparent. The latter belong to the connective tissue (neuroglia) of the cord, but present polar prolongations, like the nerve-cells.

(To be continued.)

ON THE PREVENTION AND TREATMENT OF PUERPERAL FEVER

FROM AN ETIOLOGICAL STANDPOINT.

By W. D. SCHUYLER, M. D.

THE points presented in the following considerations were partly suggested by hearing Dr. T. Gaillard Thomas's paper on the "Prevention and Treatment of Puerperal Fever," read by him before the New York Academy of Medicine, December 6, 1883, and partly by what has been offered in discussions and in papers subsequently upon the same subject.

In the first place, I was struck with the views promulgated so forcibly by Dr. Thomas in two particulars—namely, (*a*) with reference to his belief concerning the character of the puerperal, inflammatory, febrile affections—their *oneness*; and (*b*) with reference to his teaching concerning the danger or *great liability* of the puerperal woman in general, in private practice especially, to contract those maladies.

And, in the second place, I have been equally struck with the fact that—in subsequent contributions upon this most important topic in the discussions and papers alluded to, with a few notable exceptions, there has not appeared a demur or dissent to Dr. Thomas's views upon those points. Hence I conclude they must meet with very general acceptance.

Such views, however, being at variance with my own convictions, and what, from my observations of general practice, I conclude is the basis of the clinical action of most practitioners, I am led, therefore, to examine the question of their soundness by a study of the maladies in question from an etiological standpoint.

It is worthy of remark that the title of Dr. Thomas's paper, which has provoked so much, we may trust, profitable discussion, as forming the basis for a study of the puerperal maladies, is admirably chosen. And, for the purpose of illustrating the utility of *preventive medicine*, of late a favorite theme, no other class of diseases could have better been selected, as, if our ideas of the causation of these maladies are correct, their prevention comes particularly, almost wholly, within the scope of the physician himself.

To be prepared, however, to prevent the occurrence of a disease, we must entertain clear, well-defined, and correct notions of its character, and especially of the causes and laws of its development. A scientific, reasonable, and adequate method of prevention must be induced from, and rest upon, a correct interpretation of etiological facts.

It is, then, on account of the *especial bearing* of the subject upon the important matter of *prevention*, its rational application as well as successful accomplishment, that I shall proceed to examine etiotogically, first, the question whether, in the various manifestations of the puerperal maladies, we have essentially but one disease to consider—namely, whether, according to Dr. Thomas, "*puerperal fever is puerperal septicæmia*;" or whether, in the maladies these names represent, there are two affections—distinct in origin and in characteristics—to recognize, anticipate, and guard against.

Second, I shall examine the question of the liability of the puerperal woman in general to contract puerperal fever.

Third, I shall endeavor to define the indications for the rational prevention of puerperal fever and of puerperal septicæmia.

Fourth, I shall offer some suggestions relative to the treatment of these maladies, including a presentation of the indications for intra-uterine and vaginal injections, making reference to what I consider the best manner of giving

them and the best instruments to be used for that purpose.

And, lastly, I shall criticise the value of morphine as a therapeutic means in these fevers, and endeavor to point out the indications, limiting and otherwise, for its use.

In regard to the character of the puerperal febrile maladies, it is needless to say more than that there are two views entertained. On the one hand, there are those who hold, with Dr. Thomas, that puerperal fever is puerperal septicæmia, while, on the other, there are those who believe that the two names just mentioned represent two distinct forms of puerperal febrile expression, due to two widely differing causes.

In examining the first theory, as Dr. Thomas states its claims succinctly and in decided terms, we may profitably follow his plausible argument. He says: "My observations have led me to adopt the views of those who believe that puerperal fever is puerperal septicæmia." "It matters not," he goes on to say, "whether it assume the form of metritis, phlebitis, cellulitis, peritonitis, or lymphangitis, the essence of the disease is a poison which is absorbed into the blood through some solution of continuity, and which, in the appropriate soil of the puerperal condition, fructifies and produces the result known in its *ensemble* of pathological phenomena as *puerperal fever*."

And, as more clearly defining his meaning of the term "puerperal fever," he refers to the ætiology of that disease as it is set forth by Lusk ("Midwifery," p. 608), when he quotes: "It has now passed beyond the domain of dispute that puerperal fever is an infectious disease, due, as a rule, to the septic inoculation of the wounds which result from the separation of the decidua and the passage of the child through the genital tract in the act of parturition."

In setting forth the local conditions which favor the development of puerperal fever from a septic standpoint, Dr. Thomas describes the predisposing condition of the womb forty-eight hours after delivery substantially as follows: "The uterus is large; . . . the whole endometrium, covered by the grayish, sloughy-looking decidua vera, presents all over its surface an unhealthy, unclean, and diphtheritic look." . . . "The large placental site is seen raw and irregular"; "the odor of the uterine cavity is disagreeable"; "dislodging substances, mingling with the pinkish fluid which pours like an unhealthy sweat from the placental site, constitute what is called the cleansing or lochial discharge"; rents and lacerations are found throughout the generative tract. In consequence of these injuries and of absorption through them of the lochial discharge already mentioned, "the cervix is swollen and œdematous." Furthermore, he goes on to say: "In every case of child-bearing the endometrium is thus incumbered, and freed by a process of exfoliation and sloughing; in every case the cervix, vaginal mucous membrane, perineum, and vulva are, in varying degrees, lacerated; and in every case the offensive fluid called lochia poisons these freshly made, unprotected wounds." As illustrating the poisonous character of the lochia, and their competency to excite general septic action through the wounds described, he says: "Were we to take some of the lochial discharge from the vagina, after the

atmosphere has acted upon it, and apply it to an abraded surface on the finger, its irritating character would soon become evidenced by a burning sensation in the part, a smarting extending up the hand, and on the next day signs of a slight local inflammation, with a little lymphangitis, would be noticed."

Thus here we have the elements of the pathogenesis of "puerperal septicæmia, which is puerperal fever," fully and clearly set forth, and this view he confirms by a later statement, a quotation, that "puerperal fever is indeed nothing else than the infecting of fresh wounds—such as are found in every newly delivered woman—with these destructive septic materials."

These declarations leave no doubt, but clearly set forth a recognition of but one malady, which is puerperal fever or puerperal septicæmia (whichever we may choose to designate it); that this malady has an infectious character, and is generated by the septic, putrescent inoculation of the wounds which result in the genital tract from parturition.

In other words, and conversely, puerperal fever does not result except it occurs from the absorption of a septic material through a traumatic lesion.

Consistently with this ætiological theory for the puerperal febrile maladies—if I understand him—Dr. Thomas believes that every puerperal woman, wherever she may be, however she may be environed, is greatly prone to the genesis of a septic putrescent state, and therefore she is extremely liable to an attack of *puerperal fever*. This is evident from his reference to the various conditions "of the puerperal woman, which render her a prey to so many and dangerous disorders which spring up as a consequence of utero-gestation and of parturition"—namely, to her blood state—"its excess of fibrin, buffy coat when drawn by the lancet, from which two liabilities arise: First, a tendency in such blood to form thromboses in the heart and the blood-vessels, and, second, a tendency to prove a most prolific ground for the development of sepsis and zymosis"; to her greater danger from the action of the poisons of "measles, scarlatina, and varioloid, which give no very bad prognosis when they excite zymosis in the blood of the non-pregnant woman, but commonly produce death when they act upon the blood of pregnancy"; to its condition from accumulated urinary poisons which "excite convulsions"; to the condition of her nervous system, "which is in a plus state of sensitiveness and excitability, and influences which are very controllable in the non-puerperal state produce very evil results here"; to the hypertrophic condition of the uterus and its appendages, histologically and in general; and is further evident from his reference to "*prophylactic measures, which (stated in italics) he says should be adopted in all midwifery cases, whether they occur in hospital or in private practice*." Enough has been quoted—though more might be, strengthening what has been given—to elucidate Dr. Thomas's view, and the views of those who agree with him, that there is but one form of puerperal fever; that that malady results from the septic, putrescent inoculation of wounds, and that *all puerperal women are subject to it*.

The question is, Is this teaching correct? does it accord with the facts and evidence of experience? I think not.

While I can take no positive exception to the language, in a broad sense, that "puerperal fever is puerperal septicæmia"—not being able to say that in the progress and steps of the morbid anatomy of puerperal fever there may not be a stage of putrescent development and its results, while, on the other hand, we must all admit that in puerperal septicæmia there is puerperal fever as a feature of its pathological ensemble—while I can take no exception to the subsequent statement that these puerperal diseases do result from the absorption of a poison through the predisposed mucous membrane of the generative tract; while I can not deny that the progress and results of the actions set up are similar; while I recognize, on the other hand, that these maladies present the same general pathological characteristics—nevertheless, I think that in these febrile expressions we have two distinct diseases to deal with, especially when we consider them preventively.

My observations lead me to entertain the belief that the puerperal woman is subject (1) to the effects of a special contagium whose action—which is *zymotic rather than septic*—is upon and through her predisposed generative tract, and which attacks her irrespectively of whether such tract has or has not been lacerated or abraded, as a result of parturition; which contagion sets up in her what may be termed—especially on account of its contagious and specific character, and categorically at least—*puerperal fever*; and (2) that she is also liable to the development of a post-parturient fever, symptomatic, from the absorption of septic materials, and which absorption—not a contagion—is the primary step in the morbid action which follows; which malady, on account of the nature of its genesis, may appropriately or logically be termed *puerperal septicæmia*. I admit that for either of these results the *exciting cause is a poison*, and, in either, the ensemble of pathological phenomena includes a local action—inflammatory or simply absorbent—and general febrile symptoms. But, in puerperal septicæmia, predisposing states are more adynamic, and hence its early general symptoms are more diffuse and asthenic than are corresponding symptoms in puerperal fever. Again, in puerperal septicæmia results develop more directly through the blood and circulation by simple absorption of septic matter, while the poison of puerperal fever enters the system through an excited inflammatory lesion—which the reception and action (zymotic) of the contagium gives rise to, setting up febrile effects (which are essential) by its depressant and irritative action upon the nervous and nutritive functions.

The distinguishing characteristics of these poisons are: First, the poison of *puerperal fever* is a *specific or semi-specific contagium*; it communicates itself from one puerperal woman to another who may have been confined in the same locality, and within certain limits of area; and it may be communicated to another who is at a distance by a third person, and especially by the doctor. It is *endemic*. When the disease has existed in a room—varying in degree with the degree of saturation which has been accomplished—it will remain therein a certain time, and will communicate itself to a woman who may be confined in the same apartment for a varying period of

time. It particularly has dwelt in lying-in hospital wards. Its poison is heterogenous, or attacks the woman from without, and is never idiopathic; and all puerperal women who are exposed to its contagium are liable to its attack, without regard to existing intra-uterine or vaginal conditions other than that they shall be puerperal.

On the other hand, the poison of *puerperal septicæmia* is not contagious, it is not infectious, is never endemic; it is strictly idiopathic, its genesis depending upon the blood and nutritive states of the woman, upon atonic post-parturient uterine contractions, upon retained decomposing placenta or secundines, or upon abnormal and septic conditions of the lochia, and upon the absorption of septic matter from one or all of these sources through the denuded or lacerated mucous membrane of the generative tract. While the poison of puerperal fever attacks the woman from without, puerperal septicæmia (febrile) can, and generally does, develop irrespective of external causes.

Whether the contagium of puerperal fever is specific—in the sense that the poison of small-pox, of scarlatina, of measles is—is doubtful; but that it resembles the poison of surgical erysipelas, of typhoid fever, of cerebro-spinal meningitis, and is specific in the sense that the contagia of these maladies are, is quite probable. That it is a semi-malarial product, and may be developed *de novo*, I shall offer some evidence in support of later on. And that such development is hastened in the presence of surgical erysipelas, or in an atmosphere tainted with cadaveric emanations, is most plausible.

While the action of this poison, however, is not specific in the sense that it sets up a limited *cyclical*, pathological process, yet, inasmuch as it originates a characteristic contagious disease (though it can be developed anew), it may be regarded, at least and therefore, as semi-specific.

On the other hand, the action which generates puerperal septicæmia is in no sense specific; yet, without doubt, septic conditions are influenced in puerperæ by causes similar to those enumerated above: by the presence of erysipelatous or cadaveric poisons, by malaria, or by any influence which depresses vital action.

Upon no other ground of hypothesis than that of a recognition of a diverse ætiology for puerperal fever, on the one hand, and for puerperal septicæmia on the other—of a semi-specific contagium for the former, and a more general but idiopathic causation for the latter—can we explain the occurrence of those cases which develop endemically in certain localities or habitats, and especially in lying-in wards of general hospitals, by contagion, and, outside of these, the occurrence of sporadic puerperal septicæmia, idiopathic, which the general practitioner is occasionally called upon to meet.

As still further emphasizing an important point of difference in the character of the causes of these post-parturient febrile maladies, I may once more and especially refer to the fact that *all women confined within the area of influence of the poison of contagious puerperal fever are liable to an attack of the disease, notwithstanding in every such case the womb has been thoroughly emptied of its contents, the products of gestation, or whether the hand has or has not been in-*

troduced to remove adherent placenta, or whether post-parturient uterine contractions have or have not been tonically induced and sustained at the end of the third stage of labor, or whether lacerations of the generative tract have or have not occurred; while for the parturient woman in general, who is outside of or beyond the influence of such endemic region, contrary, in my opinion, to the teaching of Dr. Thomas's paper, no such fearful predisposition exists, even though her post-parturient, utero-genital condition favors the development of morbid processes.

It is well to observe, while considering the puerperal pathological results with a view of determining their essential natures and as a precaution against misleading evidence, that there is one important point to be borne in mind, which is, that we should not omit to make due distinction between the primary action, or initial lesion, and subsequent actions, processes, and lesions which develop as consequences. In either puerperal fever or puerperal septicæmia the metritis, lymphangitis, phlebitis, cellulitis, peritonitis, general fever, and blood-poisoning which form the successive manifestations of the pathological whole, are the results merely, or the sequela, of such a primary action.

As the resulting symptoms and course in either case are, macroscopically considered, very similar, as the actions involve the same structures in both maladies, it is most natural to conclude they are one and the same disease; while, if we consider the primary action only, or in conjunction with its ætiological conditions, we shall find the diseases quite dissimilar.

Upon no other method of reasoning than that of regarding the metritis, phlebitis, etc., as results, can their occurrence, more particularly the order of their development, be so rationally explained. And, while phlebitis, lymphangitis, and multiple abscess constitute the order and are primary sequela to septicæmia, vulvitis, colpitis, endometritis, metritis, etc., represent the order of the morbid progress in puerperal fever.

The primary action in puerperal fever is inflammatory, either catarrhal or diphtheritic (see Dr. Garrigues's report of the morbid anatomy of the puerperal fever cases in Maternity Hospital, "Medical Record," December 29, 1883), while in puerperal septicæmia it is evident it is simply absorbent.

The validity of the inference of an initial action, which is local primarily, in both diseases, is apparent from the almost immediate results of local aseptic treatment. According to Dr. Thomas and Dr. Hunter (discussion of Dr. Thomas's paper, New York Academy of Medicine, December 6, 1883), and my own experience since 1875, when I first practiced it with successful results, this treatment immediately checks the morbid action and, if properly applied, hastens a speedy convalescence, which, if thus early produced, is not followed by sequela. I hold that, if the action were not yet (primarily) limited, superficial convalescence would not speedily supervene, and sequela would not be prevented.

By recognizing two distinct forms of the puerperal febrile maladies, one heterogenous, propagated by a developed specific contagion, the other having its pathogenesis

in idiopathic conditions and non-contagious (both arising from infection, however, through the generative mucous tract), in either or both of which the morbid action is primarily superficial and local—if such pathological data are correct, as I shall maintain—we thereby simplify our conceptions of the requirements of necessary preventive indications.

As bearing upon the question of preventive treatment for these maladies, and particularly as having reference to the reasonable as well as necessary indications for such treatment; furthermore, as influencing our judgment relative to the character or nature of the maladies we are discussing, it is necessary to clearly determine the predisposition of the puerperal woman in general to an attack of these maladies—either of puerperal fever or puerperal septicæmia. As a matter of fact, while it is safe to carry out the prophylactic measures advocated by Dr. Thomas in every case to which one is called, "both in hospital and in private practice," while it is equally safe to treat every woman "who is about to bring forth as one about to go through the perils of a capital operation"; yet if facts and experience show that such measures are not *always* necessary—that the indications for such measures are not of ordinary occurrence, but are, on the contrary, most unusual—then, in view of the impossibility of being able to put them into practice in a large percentage of cases, from lack of time, means, or concurrence on the part of others, or on the part of the patient herself, their adoption *in every case as a necessity* is both irrational and unscientific.

Rational and scientific preventive measures (*and such only will be generally adopted*, and therefore only can work valuable results) must have their indications in correct data, both as to the degree as well as the character or gravity of the dangers to be avoided.

The question of first importance in this connection, then, is relative to the predisposition of the puerperal woman in general to contract these maladies. Is the puerpera, as met with in general private practice, sufficiently predisposed to contract either puerperal fever or puerperal septicæmia, to constitute a reasonable or obligatory cause to the physician for the adoption of elaborate and especial preventive measures against such danger?

I can not believe with Dr. Thomas that the puerperal state as such, and in itself uninfluenced by contagious causes, renders the woman an easy prey to so many and dangerous disorders. That hyperinosis is a characteristic of the blood of the parturient woman is generally understood; but that such state, combined with a tendency of the blood to form a buffy coat when drawn by the lancet, is a cause for the "formation of thromboses in the heart, or proves a prolific ground for the development of sepsis and zymosis" in her, is, in my opinion, not sustained by evidence derived from common experience.

Though the statement may be trite, yet I must declare that I have confined too many women in the midst of surroundings where conditions were anything but hygienic, without untoward consequences, and with normal convalescence, to warrant me in any other conclusion than that the parturient state *is not especially* prone to take on either

zymotic or septic conditions, or to develop special inflammatory and febrile states. That "the nervous system of the parturient woman is in a plus state of sensitiveness and excitability, and that the influences which are very controllable in the non-puerperal state may produce very evil results in her," as stated by Dr. Thomas, is true in some respects; that an accumulation of urinary poisons in her blood may produce convulsions, and that untoward moral influences may produce violent mania (also probably traceable to some degree of uremia), are points only too often illustrated, but that these conditions especially predispose her to develop puerperal fever, has not yet been causatively shown.

And that the parturient female is not always or more seriously affected from the action of measles, scarlatina, or varioloid than the non-parturient, and especially that one of these complicating diseases may occur and not excite or generate puerperal fever in her, I have the notes of a case which came under my charge to testify:

In this case the woman was confined by a midwife. She had, according to the history, a prolonged, hard labor, and, with delivery, suffered a complete laceration of the perineum. The evening after her delivery she felt very well; the following morning headache occurred, the lochia became scanty and almost ceased, and a general malaise with vomiting was experienced. The morning of the third day the patient noticed an eruption on her arms and a great itching of the reddened surface. The evening of this day I saw her for the first time. Her body was covered with a dark-red rash, which faded upon pressure, but quickly returned. Wales readily developed upon its surface. Her face was only deeply suffused; the tongue presented the characteristic strawberry, brownish-red appearance. Her throat was sore, the tonsils and mucous membrane were swollen, grayish patches were over the tonsils. Her water was dark and scanty. She experienced much malaise, was thirsty, her pulse was 140, and her temperature was 104°. For two days thereafter her condition did not greatly change, but on the morning of the sixth day her symptoms abated, her pulse was 120, and her temperature was 99.5°. Her mind, which had wandered slightly, was normal, the tongue was moist and lighter in color, the eruption was fading over the chest, and evidently she was convalescing. During this time there were no other uterine symptoms except diminished lochia. On the ninth day desquamation began, and was markedly abundant for the week following. On this day also (the ninth) the pulse stood 100, temperature 98.5°.

On the tenth day her bowels were loose; pulse and temperature same. Eleventh day, eight o'clock A. M., pulse 104, temperature 100°. Twelfth day, pulse 100, temperature natural. Thirteenth day, pulse 120, temperature 103°; had pain in the calves of the legs. Fourteenth day, pulse 116, temperature 99.5°; discovered an erysipelatous inflammation had developed upon the posterior surface of the lower third of the left leg, that quickly caused a diffused abscess at the point first attacked, which broke and discharged, but not freely. The erysipelatous action quickly extended to the whole of the posterior surface of the leg; the knee was much affected, but, the inflammation being held in check, it did not develop pus at that point. I have to state that this patient had scarcely any nursing, that which she received being given by her husband, who, to keep his place and earn the necessary means to provide for her wants, was obliged to leave her alone thirteen hours out of every twenty-four; and that, from lack of the necessary attention and of a carefully

provided diet, from loneliness and the necessary care as to cleanliness, and lying in a low, dark, and small room, her condition was almost hopeless. So on the sixteenth day I made an effort to have her removed to a hospital, where she might have better care. However, having an erysipelatous inflammation, she could not be admitted to Roosevelt Hospital; and, having been in the country but six months, and therefore an enigrant, she could not be taken at Bellevue. It being deemed hazardous to send her to the Island Emigrant Hospital, it was decided to try to keep her where she was.

On cod-liver-oil emulsion and moderate doses of quinine, the patient appeared to mend. On the twenty-first day her pulse was, however, still 120, temperature 100°. On the twenty-third day, pulse 84, temperature natural. Her appetite was very good and bowels moving regularly. From long and continuous lying upon a hard straw mattress, on the twenty-fifth day it was discovered that a bed-sore had developed over the sacrum, of which she had before given no indication. From this out her strength and appetite failed; the pulse varied between 100 and 120 per minute, the temperature remaining at about 100°. On the thirty-second day the temperature was 101°. On the thirty-third day it was 100°, and the patient was then removed to St. Luke's Hospital, where she lingered on several days and died.

At no time in the course of this sickness were there manifest symptoms of trouble in the generative tract. Although speculum examinations were not made, yet palpation and deep pressure were practiced daily, always with negative results.

I submit that this case of difficult parturition, of extensive perineal laceration, of subsequent scarlatina, followed by erysipelatous inflammation and a developed bed-sore, of inefficient nursing, of inadequate nutrition, helplessness, loneliness, and filth, in which, as evidenced by the temperature given, there was no puerperal fever, but in which, possibly, not, however, from any morbid action or results in the generative tract, but most likely from the erysipelatous abscess and from the bed-sore, septicæmia developed, shows, so far as one well-marked case can, (1) that the parturient state is not particularly prone to take on those endometrial inflammatory processes which excite puerperal fever on the one hand, or to develop a generative septic condition which excites puerperal septicæmia on the other; (2) that something more than scarlatina, and erysipelas added, is required to generate puerperal fever, and that even these poisonous maladies, acting in a puerpera, who has in addition a lacerated perineum, are not always adequate to set up a septic or zymotic condition in the generative tract, or do not always cause puerperal septicæmia. Lastly, the case shows that scarlatina does not always cause death when it acts upon the blood of pregnancy.

Again, while the uterus at term comprises an enormous development of blood-vessels and lymphatics as a part of its functionally hypertrophic state, as illustrated by sketches exhibited by Dr. Thomas, yet I hold that this condition of the generative organ does not especially predispose to a dangerous degree of absorption, and hence does not particularly conduce to the development of puerperal fever, or even puerperal septicæmia. And I hold that this negative result is due to the fact that the post-parturient, tonic contractions of the womb which so compress the functionally developed organs that absorption from their open mouths can not occur. And, as a further result of com-

pression from uterine muscular contraction, such a degree of endometrial anæmia is caused as leads to a more or less rapid fatty degeneration, especially of the hypertrophied elements, and hence to the more complete and early cessation of their function. It is quite probable that it is by this action, early compression of the vessels and lymphatics (which is also the safeguard against post-partum hæmorrhage), that we can account for the protection from absorption and septic poisoning by decomposing clots, and by breaking down retained placenta, which often remain in the womb or vagina until they become putrid and most offensive, thought without causing serious injury. If it were not for this protection, the lochial discharge, which is sometimes very irritating, acting upon the system through the many lacerations over which it must pass, would, more frequently than such result happens, set up septic trouble.

I would also add, concerning the teaching that the lochia are in themselves very poisonous and a prolific cause for the development of sepsis and zymosis, that the statements made relative to the many lacerations which are caused in the course of the generative tract, considering that these lacerations must be bathed for some days in the cleansings, and the relative infrequency of septicæmia from this cause—both in a lying-in and in private practice—constitute its ample disproval.

From the foregoing considerations I would submit the opinion that in general the generative tract of the parturient woman, as she is met with under normal conditions, in private practice, is not especially predisposed to take on septic or zymotic degenerative action; and, therefore, under normal conditions, and where she has not been exposed to the contagium of puerperal fever, the parturient act (being a natural function) does not jeopardize the woman, and does not offer indications for an unusual, elaborate, or dread-inspiring institution of preventive measures.

(To be continued.)

A CONTRIBUTION TO THE STUDY OF CONGENITAL SYPHILIS.*

By JOHN N. MACKENZIE, M. D., BALTIMORE,
SURGEON TO THE BALTIMORE EYE, EAR, AND THROAT CHARITY HOSPITAL.

I HAVE selected the case, whose essential features are given below, from my note-book, not only on account of its peculiar interest, but also to serve as the text for some remarks on the manifestations of congenital syphilis in the throat, and their behavior under the influence of acute disease.

Agnes C., aged eight, the child of syphilitic parents, was brought to the London Hospital for Diseases of the Throat and Chest in the latter part of September, 1879. Her history was as follows: Healthy at birth. When five weeks old, lost power in the right upper extremity. This lasted for five weeks, during which time she had no control over the limb. When eight weeks old, contracted a diarrhœa which lasted uninterruptedly for nine months. With the diarrhœa, round, irregular, elevated patches of a red color appeared on the back and buttocks, which were associated later on with an eruption around the anus and genitals.

* Read before the American Laryngological Association, May 12, 1884.

These lesions disappeared some months afterward with an attack of measles. When an infant, would cry out in the night, clinch her thumbs, and burrow her head in the pillow.

From her first to her third year, an interval of perfect health. At the age of three, inflammation, with a cloudy condition of the right eye, appeared, followed in two weeks by implication of the left. The eyes remained inflamed for two years. (The patient's letter from the Royal Ophthalmic Hospital states the condition to have been keratitis.) At the expiration of this time both upper eyelids became completely paralyzed, so that she had no power over them whatever. She could lift them up with her fingers, and frequently did so; but the muscular control of the lids was gone. There was no inflammation of the eyes beyond some remains of the keratitis at the time, and their exposure to light gave rise to no irritation. The mother noticed nothing wrong about the eyeballs during this period. With the ptosis the child complained of intense occipital cephalalgia; convulsive movements occurred during sleep, during which she would contract her brows and rub her head with her hands, leading the mother to suspect trouble with the brain. These symptoms lasted for over a month, at the end of which time, together with the paralytic condition of the lids, they completely disappeared. (During this period she was under intelligent medical supervision, but I am unable to discover what treatment was adopted.)

When they had passed away, the mother noticed for the first time that the right eyeball was turned inward toward the nose, and that she had become deaf in the right ear, from which there issued a slight but constant discharge. Shortly afterward a little white spot appeared on the left tonsil, which slowly ulcerated, the ulceration involving the whole of the back portion of the throat. At the same time she complained of great difficulty in deglutition and pain in the bones, the cervical glands became enlarged, she spoke in a nasal tone of voice, and had a profuse discharge from the nose. During the period of sore throat there was suppurration of the right lachrymal sac, which opened, and continued to discharge for eighteen months. The left sac then became inflamed, suppurated, and ruptured spontaneously, and the discharge has been gradually diminishing in quantity since. The ulceration of the throat healed slowly; would constantly break out afresh; in fact, it never completely cicatrized.

In August, 1879, the child became suddenly aphonic from exposure to cold, and, in the latter part of September, was brought to the hospital suffering from dysphagia and dyspnœa of several weeks' duration.

Condition on Application at the Clinic.—Large head, prominent frontal eminences; cloudy cornea, opacity of the right lens; right internal strabismus; marked flattening of the nasal bones and prominence of the lower jaw; the remains of a dacrocystitis of the left side. The pegged condition of the teeth is absent. Mucopurulent catarrh of nose and middle ear. On looking into the mouth, the whole of the hard palate is seen to be in a state of active ulceration, and there is necrosis with perforation of its central portion. The palatal destruction extends over the anterior arch of the alveolar ridge, involving the bone to a limited extent. The soft palate, uvula, and anterior faucial pillars are completely destroyed, and the posterior wall of the pharynx is the seat of a large, angry-looking ulcer which extends into the naso-pharynx as far upward as the view extends. The patient has to keep her handkerchief constantly to her mouth to absorb the discharge, which accumulates with great rapidity.

Laryngoscopic examination is not possible; but there is absolute aphonia, with dyspnœa, and the glands at the cornua of the hyoid bone are hard and swollen.

Liquids and solids, which are not finely divided, return through the nose, and the little patient complains of cough, pain in the head, and night sweats.

The ulceration continued to advance, in spite of tonic and anti-syphilitic treatment, until the 18th of October, when the patient was seized with scarlet fever of a mild type. With the appearance of the exanthem the ulceration in the throat began at once to heal, and, when the stage of desquamation was reached, cicatrization was complete, the dyspnoea and dysphagia mitigated, and the voice restored.

Shortly after convalescence the ulceration became again active, and in the early part of the following December a severe, acute pneumonia supervened. The pulmonary inflammation, with which she was confined to the house for four weeks, seemed to exercise no appreciable effect upon the palato-pharyngeal ulceration, which only cicatrized some weeks after resolution had taken place.

The throat then presented the following appearances: The hard palate was covered with cicatrices, and there was a small point of incipient ulceration at its posterior portion. The palate was continuous behind with a dense mass of cicatricial tissue which completely filled the fauces and pharynx, and in which all trace of the original anatomy of these parts was lost. In its center a small, oval depression existed, which communicated with the parts below by an aperture, through which the tip of the little finger could not be passed. From this central sulcus, which represented the remains of the pharyngeal cavity, a small contracted passage led into the naso-pharynx which would just admit an ordinary probe. The child breathed entirely through her mouth, upon closing which, the respiration had a loud, roaring sound. By forcible expiration she could drive a faint column of air through the nose.

Before passing to the consideration of the subject to which I desire to call special attention, there are two features in the above case that deserve particular notice.

While deep ulceration of the pharynx (I refer to the *lower* pharynx) is not rare in congenital syphilis, such a degree of resulting stenosis is excessively uncommon. I know of but two similar cases. In the one,* a mere slit formed the only communication with the structures beneath, and in the other† the pharynx was so constricted as to scarcely admit the point of the little finger.

Of great interest, too, is the *paralysis of both upper eyelids*. The history of the case would point to a cerebral lesion as its probable cause, possibly a gummatous deposit in the course of the oculo-motorius nerve. The subsequent paralysis of the abducent and the symptoms referable to the organ of hearing on the same side may also be susceptible of a similar explanation. Any reasonable doubt as to the syphilitic nature of the paralysis would be dispelled by the easy exclusion of other causes and the curative effect of (presumably anti-syphilitic) treatment. The case, then, adds one to the short list of affections of the cranial nerves in hereditary syphilis observed by Graefe,‡ Barlow,§ Dowse,|| and Galezowski.△

In the "American Journal of the Medical Sciences" for October,* 1880, I called attention to the frequency with which the throat is involved in congenital syphilis, and gave a systematic description of the lesions which are found in the pharyngo-bronchial tract and œsophagus during the course of that disease. In opposition to the then generally received doctrine, I ventured to maintain, as the result of careful investigation of the subject, that, so far from being rare, as was generally supposed, laryngeal affections in congenital syphilis are among the most common and characteristic of its pathological phenomena, and that the invasion of the larynx may be looked for with the same confidence in the congenital as in the acquired form of the disease. Further experience and the study of cases recorded by others have only served to strengthen the positions taken in the paper referred to and the views there expressed, for which I must refer to the original.

Among other things, the following conclusions were reached in reference to deep, destructive ulceration of the oro-pharyngeal cavities: 1. That deep ulceration may invade the palate, pharynx, and naso-pharynx at any period of life from the first week up to the age of puberty. Thus, of thirty cases analyzed with reference to the period of invasion, fourteen occurred within the first year, and ten within the first six months of life, the remainder occurring at periods more or less advanced toward puberty. 2. When the eruption of inherited syphilis is apparently delayed until the latter period, that lesions of the palate and pharynx are found with a peculiar constancy, and often first attract attention to the existence of a diathesis of which they are the sole pathological expression. 3. That females are attacked more frequently than males. Thus, out of 69 cases of pharyngeal ulceration, 41 occurred in the former sex. 4. That ulceration may occur in any situation; but its most frequent seat is the palate, for which it exhibits the closest elective affinity. 5. That, when situated at the posterior portion of the hard palate, the tendency is to involve the soft palate and velum, and thence to invade the naso-pharynx and nose; while, situated more anteriorly, it seeks a more direct pathway to the latter, which is established by perforation of the bone. 6. That the next most common seats of ulceration in order of frequency are the fauces, naso-pharynx, posterior pharyngeal wall, nasal fossa and septum, tongue, and gums. 7. That ulceration, especially that of the palate, shows a disposition to centrality of position, together with a special tendency to caries and necrosis of the bone, a fact probably explicable by the great vascularity of the periosteum and medullary membrane in youth. 8. That the tendency to necrosis exists at all periods of life, but especially in early youth, when it is more destructive and less amenable to treatment. 9. That while deep pharyngeal ulceration generally precedes or co-exists with similar affections of the larynx, the latter occurs too without evidence of pre-existing pharyngeal lesions. 10. That laryngeal ulceration does not commonly follow the pharyngeal destruction of so-called latent syphilis, those palato-pharyngeal ulcerations found in tardy congenital syphilis having

little tendency to invasion of the larynx, but rather to implication of the nasal pharynx and nose. 11. That simultaneous or consecutive ulceration of the palate, pharynx, and nose seems to be characteristic of syphilis, or at least occurs more frequently in this than in any other disease.

I bring these facts again into prominence because they differ from commonly accepted views, and because they possess at least a certain value, by reason of the method by which they were obtained. I desire also to reiterate what was said in connection with the confusion of these lesions with so-called "scrofulous" ulceration. Without entering into a discussion of the subject, suffice it to say that there is no just ground for belief in an ulcerative scrofulide of the throat. It needs only the most superficial review of the writings of those who maintain its separate existence to show the utter confusion which prevails as the result of erroneous views, handed down among the traditions of an obsolete pathology.

It is obviously a point of great practical importance that this fact should be recognized, and especially in view of the rapidly destructive tendency of inherited syphilitic ulceration in the oro-pharyngeal cavities and larynx.

The throat ulceration of congenital syphilis not only exhibits a special tendency to rapid invasion of the deeper tissues; it often possesses an inherent virulence which places it apparently beyond the reach of therapeutic control. This is markedly true of the ulceration which occurs in the earlier years of life. Cases are now and then encountered where the ulcers stubbornly refuse to cicatrize, or do so sluggishly and imperfectly, healing at one point and becoming simultaneously active at others. *Under such circumstances, when remedial measures are apparently of little or no avail, they sometimes cicatrize, as if by magic, on the accession of an acute disease.* It is to this that I wish to direct particular attention.

The clinical study of the cases upon the analysis of which the report referred to was based disclosed certain striking facts in connection with the influence of some of the ordinary infectious diseases of childhood upon the progress of the inherited syphilitic affection. From the historical narratives furnished by this particular group of cases, it would appear (1) *that, while congenital syphilis affords no absolute protection against certain acute infectious diseases, its existence in the individual seems often, other things being equal, to mitigate their severity and exert a favorable influence on their course;* (2) *that certain acute diseases, accompanied by an exanthem, favor the dissipation, at least temporarily, of the throat and other manifestations of the disease;* (3) *that while at no period of the disease is the child exempt from these affections, they are more liable to be contracted during the period of latency—that curious interval of apparent health in congenital syphilis which Cazenave has poetically called the sleep of the virus.*

These remarks are limited to scarlet fever, measles, and chicken-pox, but they could doubtless be extended to embrace others of the exanthemata; or, in other words, to those diseases which present a certain analogical resemblance to syphilis.

They do not apply, for obvious reasons, in the case of

excessive virulence of the syphilitic cachexia or malignant epidemic influence of the intercurrent disease.

Of special interest is the effect produced by acute febrile disease upon the throat lesions of congenital syphilis. *Chronic inflammatory conditions and ulceration of the larynx, pharynx, and nasal passages are often influenced in a remarkable manner through the presence in the individual of an intercurrent febrile affection. This is, moreover, eminently true of those acute blood diseases with special tendency to local manifestations in the throat, such as scarlet fever, measles, diphtheria, etc. According to personal experience, scarlet fever and measles exert, as a rule, a favorable influence on the course of the throat affection, their supervenience being of itself sufficient to cause its complete disappearance. The poisons of the two diseases in their circulation in these regions appear to be mutually destructive, and the throat escapes by virtue of such reciprocal antagonism.* The cure here may be permanent, or relapses of the inflammatory or ulcerative process may follow the removal of the antagonistic influence of the intercurrent disease.*

These remarks do not apply to diphtheria. When this affection supervenes during the existence of lesions in the throat, the patients rapidly succumb to the disease. The existence of syphilis in the child apparently increases the tendency to membranous formation; indeed, in some instances, apart from the presence of the diphtheritic process, there seems to be a special tendency to fibrinous formation in the nose and retro-nasal space.

The influence of acute disease upon the manifestations of constitutional syphilis is a subject which has received some attention at the hands of syphilographers, especially certain of the French school; but very little is known as yet, beyond the empirical fact, that the lesions of that disease, and especially the cutaneous syphilides, are often modified by the introduction into the blood of the virus of an intercurrent febrile affection. This modification may consist either in the permanent or temporary dissipation of existing syphilitic lesions, or in the exaggeration or intensification of the morbid process. Thus, for example, various syphilitic affections, such as skin eruptions, exostoses, etc., have been observed to disappear during the course of erysipelas,† acute rheumatism,‡ cholera,§ variola,|| febrile furunculosis,^ etc. Laségué ¶ has recorded a case of ulceration of the pharynx and tonsils which disappeared during an attack

* It is quite possible that this may also be true of other mucous surfaces of the body.

of erysipelas, while in a similar one observed by Martellièrre* a fatal result ensued from that disease. The dissipation of syphilitic eruptions has also occurred during pregnancy,† and as the result of vaccination,‡ and there is a case on record where the latter apparently exerted a curative influence in caries of the pharyngeal vault.*

The remarkable power of erysipelas over the cutaneous syphilides has suggested its artificial production as a therapeutic agent in these affections,|| while their behavior under the operation of the vaccine virus led to the now almost forgotten practice of Lukonski.^A It has, finally, even been proposed by an enthusiastic pupil of M. Hardy to inoculate the poison of small-pox in cases of syphilis which have resisted all other methods of treatment.()

It is sufficiently evident, then, that a reciprocal antagonism exists between the poison of syphilis and that of a number of acute diseases. By what pathological law this is brought about is, in the present state of our knowledge of the mutual relations of disease, a matter of pure speculation. In the case whose history has been recited above it is interesting to contrast the curative effect of the exanthematous fever on the ulceration in the throat with the persistence of the latter during the acute pulmonary affection.

This remarkable influence of the febrile state upon syphilitic inflammation and ulceration of the nasal passages and throat is also, in a measure, true of simple inflammatory conditions of these cavities. It were foreign to the purpose of the present article to elaborate this latter and cognate subject, and I shall therefore simply offer for your consideration the fact that *simple catarrhal inflammation of these regions occasionally disappears completely, and is permanently cured during the course of an acute febrile disease.* Whether this occur as a phenomenon of so-called "substitution," or as the result of a profound impression made upon the nutrition of the parts by virtue of which abnormal secretion is arrested and the inflamed tract placed in a condition favorable to resolution, can only be determined by the accumulation of more exact scientific data concerning the reciprocal antagonism of pathological processes.

Without, then, attempting any special explanation or generalization, I present the foregoing observations from my clinical experience as a contribution to the study of an interesting but imperfectly understood subject.

DISCUSSION.

Dr. J. H. HARTMAN.—I have seen a case of congenital syphilis, in a child four years old, in the course of which an attack of measles supervened, which aggravated the ulceration in the nasopharynx. The child recovered from the attack of measles, but the throat was left in worse condition than before. True, this

was only one case; still, it goes to show that such cases are not always benefited or controlled by an attack of one of the exanthemata, as Dr. Mackenzie has stated.

Dr. F. DONALDSON said he had understood Dr. Mackenzie to question the existence of scrofulous ulceration of the throat in young children, not connected with congenital syphilis. He related a case, now under his care, that of a child five years old, the son of a healthy farmer, who had, with a large ulcer of a scrofulous character over the soft palate, unmistakable evidence of scrofula, such as enlargement of the lymphatic glands, etc., and none of the symptoms usually associated with congenital syphilis.

Dr. F. I. KNIGHT.—My experience regarding these cases, while limited, has caused me to feel very much as Dr. Mackenzie does—namely, that a careful search for the origin will reveal a history or evidence of syphilis, and, if not of syphilis, of tubercle. We can not always get a history of syphilis, nor can we always do so in the adult presenting certain symptoms, but antisiphilitic treatment gives results which justify us in considering this the nature of the disease.

The PRESIDENT.—After seeing a large number of cases of the character referred to in the paper, in dispensary practice, my conviction is a growing one that, so far as the mucous membrane of the air-passages is concerned, there is no difference between congenital syphilitic and scrofulous ulceration. I formerly made a distinction, recognizing the action of two constitutional tendencies in the production of such affections, but now make no distinction between scrofulous ulceration of the fauces and ulceration of the same parts from syphilis. I should have been glad had Dr. Mackenzie gone a little more fully into the question of treatment. I am so far convinced of the identity of the two conditions that of late years I have depended almost entirely upon the administration of mercurials, and in many cases the result has been eminently satisfactory and such as to strengthen the idea of the identity of the two diseases.

Dr. MACKENZIE closed the discussion, and said: I especially avoided generalizations in my paper, and only stated that, in my experience in this class of cases, the ulceration was often cured by an intercurrent disease. I further stated that this remark did not apply to malignant epidemic influence, or so-called syphilitic cachexia. In Dr. Donaldson's case, I should like to ask how a diagnosis was to be made between syphilis and scrofula. Dr. Knight has pointed out the difficulty of arriving at the historical facts, and we must therefore rely upon our powers of physical diagnosis. With regard to treatment, I generally give mercurials and the iodide of potassium, and apply iodoform locally. If the ulcers heal while the patient is taking cod-liver oil, it is not evidence that the cause was scrofula and not syphilis, for cod-liver oil may act as a tonic in various conditions.

A CASE OF SUCCESSFUL EXTIRPATION OF THE THYROID GLAND.*

By FRANK W. ROCKWELL, M. D., BROOKLYN,
SURGEON TO ST. MARY'S AND ST. JOHN'S HOSPITALS.

The specimen presented this evening was removed from Fanny —, a Bavarian, eighteen years old, who entered my service in St. Mary's Hospital in December, 1883, with the following history:

When about three years old a tumor was noticed on the right side of the neck, which had been slowly but steadily increasing ever since.

* Read before the Brooklyn Pathological Society, April 10, 1884.

About three months previous to admission a similar growth made its appearance to the left of the trachea, and during this time both tumors had increased to such an extent as to greatly interfere with deglutition and respiration; she had had repeated attacks of vertigo and paroxysmal dyspnoea, and had been under the care of different surgeons, and in St. Francis's Hospital, New York, and the City Hospital, Brooklyn.

On admission, she was well nourished, with good appetite and digestion, but in constant fear of dying during one of her suffocative attacks.

A tumor the size of a large orange occupied the inferior carotid triangle on the right side, and a smaller one a similar position on the left.

On examining the masses during efforts at deglutition, very slight movements could be detected as accompanying the act, but lateral motion could be elicited with comparative ease.

The right growth could be easily defined, except at its posterior border, where it shaded off into, and was lost under, the belly of the sterno-mastoid muscle.

The patient was at once put upon full doses of the potassium iodide, and the quantity administered was gradually increased, until on January 24th she had reached the amount of one hundred and forty grains per diem, when it was used in diminished doses for a few days on account of irritability of the stomach and the supervention of acne pustules.

During the preceding month, beginning January 2d, she had, in connection with this treatment, taken that which consists in giving gradually increasing doses of the sulphate of strychnine, beginning with very minute doses and increasing to a point of tolerance.

Local treatment of various kinds was adopted. At first the inunction of the ung. potassii iodidi; subsequently the ointment of mercuric biniode in combination with prolonged exposure to the rays of the sun, as advocated by Dr. Monatt, of Bengal; these failing, Professor Stoerk's injections of alcohol, and also Lücke's of strong tincture of iodine, were attempted, but discontinued after a few trials, as they produced severe pain and inflammation, but with no beneficial results upon the cystic portion of the growth, for the obliteration of which they were employed.

By February 1st the patient was taking two hundred grains of iodide a day, with no benefit except that during her stay in the hospital her vertigo and dyspnoea had slightly improved—a result probably as much due to her quiet life in the ward as to any drug administered.

February 6th.—She expressed her determination to have an operation performed for her relief or leave the hospital, her conclusion having been reached after many conversations with myself and my colleagues upon the dangers of the procedure and its uncertain results.

Accordingly, on February 11th, she was placed under ether, and an incision made reaching from the hyoid bone to the sternal notch.

The superficial cervical fascia and platysma were divided cautiously, and the superficial layer of the deep cervical fascia expanded over the growth was reached and split up on a director.

The capsule of the gland was now seen filled with distended veins and arteries, which, inosculating in all directions, made any manipulation in their vicinity extremely dangerous, as many of them were as large as the radial or ulnar artery. I had, however, determined, before undertaking the operation, to avail myself of all the advantages which a systematic employment of forcipressure and the use of catgut ligatures might give me, and I accordingly began a careful enucleation of the gland, ligating all vessels in two places and cutting between them or holding them with Péan's forceps as they bled, and securing them at my leisure. In this way I easily though slowly dissected the tumor away until I reached the sheath of the internal jugular vein, to which the gland was intimately adherent; the vein, turgid with blood and pulsating from the movements of the artery beneath it, was so difficult to reach that I for the time being abandoned the dissection in that direction and began working toward the median line. By pursuing the same plan I gradually freed the gland from firm adhesions, both vascular and fibrous, to the trachea and oesophagus, and then, having reached and ligated the inferior thyroid and isthmus, I began, from the upper border of the growth, to free it from the carotid sheath.

The superior thyroid was now ligated, and the tumor slowly and carefully dissected away from the carotid and internal jugular and lifted out of its bed. Up to this time *not more than two ounces of blood had been lost*, although, on removing the growth, the trachea, oesophagus, internal jugular for about two inches, and common carotid arteries were all easily distinguished and lying bare in the wound. The left lobe of the gland was not removed, as another tedious dissection would have been necessary, and it was so slightly affected as to interfere neither with the patient's health nor with her appearance.

Vessels on which temporary ligatures had been applied were now secured with catgut, and I was about to close the wound when I found, on examination, that the catgut ligature on the inferior thyroid was not secure, owing to a slight retraction, apparently, of the cut end of the vessel.

On seizing the vessel with a pair of forceps, the ligature came away entirely, and in a moment a hæmorrhage occurred which showed vividly, to both myself and those who were present, how perfectly helpless a surgeon must be in the presence of such a case when operating by the usual method of "attempting as rapidly as possible to reach the pedicle of the growth and secure the principal vessels."

The artery, however, was secured at once, and the wound irrigated with the mercuric-bichloride solution, 1 to 1,000, and closed. As the dissection had necessarily invaded the space lying behind the clavicle, a button-hole was made below the incision, and through this a drainage-tube was led up into the bottom of the wound and secured with a horse-hair suture. Two long catgut sutures were left as guides in case of secondary hæmorrhage, one leading to a large vessel in the isthmus of the gland, the other to the inferior thyroid; their ends were brought out of the opening by the side of the drainage-tube. The wound was closed with horse-hair sutures, and covered with a pad of naphthalinated sawdust and a gauze bandage.

Antiseptic precautions were adopted throughout the operation, with the exception of the spray. π x of Magendie's solution were given subcutaneously, and the patient, who had been under ether nearly two hours and a half, and was suffering somewhat from shock, was put to bed. In the evening, under moderate stimulation, her temperature was 99.5° F., pulse 99.

12th.—Patient disarranged the dressings during the night, necessitating their renewal. Temperature 100.5°, pulse 120. Some soreness about the throat.

13th.—Some pain on swallowing, though liquids and semi-solids are taken with relish. Temperature 100.25°.

14th.—Drainage-tube, and all but four of the sutures, removed. Feeling very comfortable. Temperature 98.5.

16th.—Complains of some pain beneath right ear. Temperature 101.75°. A patient with erysipelas has been removed from the bed next hers in the ward. By evening the temperature had fallen to 99.75°. Passed a quiet night under the influence of Magendie's solution (π x).

17th.—Remaining sutures and the ligature from the isthmus came away. A little stiffness in the neck.

18th.—Slight discharge from opening made for drainage.

20th.—New dressing applied; discharge a little more free. From this date, however, all went well until January 28th, when the ligature came away from the inferior thyroid. From this time the slight opening left was dressed with naphthalin ointment, and rapidly closed.

March 2d.—Wound entirely healed. Patient has been going about the wards for several days. The left lobe of the thyroid seems to be diminishing in size, and she is free from all symptoms of her former trouble.

14th.—Left the hospital to resume her duties as a house servant.

The specimen removed weighed exactly twelve ounces avoirdupois, consisting of hypertrophied glandular tissue, and contained cysts. Projecting from its upper border was the large open trunk of the superior thyroid, and in various directions upon its surface could be seen intersecting branches of large veins with thin walls; at its inferior border and at the point of its attachment to the isthmus, other vessels had been ligated, and their stumps still remain. The growth is evidently a cysto-adenoma, the original thyroid vesicles having become dilated and their viscid contents rendered fluid by the ordinary processes which accompany such changes in epithelial glands.

One word in regard to the present position of the operation of extirpation of the thyroid gland.

So far as my own knowledge goes, all prominent surgical authorities of recent date, with one exception, condemn the operation unhesitatingly.

In reviewing the literature of the subject previous to the operation, I could find no support for the attempt except the clinical facts adduced by Watson, of Edinburgh, and Billroth, Kocher, and the other German operators. Since then my attention has been called, through the kindness of my friend Dr. G. V. P. Convery, to the valuable work of Dr. Paul Liebrecht, of Brussels, who, from a tabulated account of all the cases he could collect, gives the following statistics:

Operations by German, Austrian, and Swiss surgeons...	226
“ “ French surgeons...	34
“ “ English “	30
“ “ American “	16
“ “ Italian “	10
“ “ Prussian “	3
“ “ Swedish “	1
“ “ Belgian “	2
Total.....	322

Of this large number one is surprised to find that 250 were cured, 64 died, 2 were not completed, and in 5 the result was uncertain.

To these are added, without details, a series of 34 cases with 5 deaths, making a grand total of 356 cases with 69 deaths, or a mortality of 19.39 per cent. After alluding to 400 as the probable number of operations actually known to have been performed, the author is quoted in the “American Journal of the Medical Sciences” for October, 1883, as saying that the actual mortality from causes incident to the operation itself does not exceed 8½ per cent. In this statement he is supported by Watson, who maintains that operations conducted on his plan—the one detailed in the first part of this paper—prove fatal in only about 7 per cent.

Surely it would seem, from this surprising array of cases, that, in spite of the traditions of the profession, thyroidectomy, like ovariectomy, would soon find its place among recognized surgical operations, and be resorted to under the same conditions as those which govern us in the selection of cases for other forms of operation on morbid growths.

Book Notices.

Elements of Surgical Pathology. By AUGUSTUS J. PEPPER, M. S. M. B. Lond., F. R. C. S. Eng., Surgeon to St. Mary's Hospital, etc. Illustrated with eighty-one Engravings. Philadelphia: Henry C. Lea's Son & Co. Pp. xii-503.

In this small work we have a contribution to surgical literature of positive value. It is not pretentious, aiming only to supply what is necessary for the student to know when he comes up for examination, but it contains much more than practitioners generally do know, and will serve exceedingly well as a book of reference. It embodies a great deal of matter, extending over the whole field of surgical pathology; its form is practical, its language is clear, and the information set forth is well arranged, well indexed, and well illustrated. Such works can not be exhaustive—they are not intended to be—what matter they contain has to be carefully selected, and the selection constitutes the chief charm of this particular book; the student will find in it nothing that is unnecessary, and will miss but little that is of practical importance. The author has devoted a few lines or a few pages, as the case may be, to each subject, and the list of subjects covers the whole range of surgery. The book supplies a very manifest want, and should meet with success.

THE
NEW YORK MEDICAL JOURNAL,
A Weekly Review of Medicine.

Published by
D. APPLETON & Co.
Edited by
FRANK P. FOSTER, M. D.

NEW YORK, SATURDAY, MAY 31, 1884.

THE PROPOSED NEW CITY PARKS.

As many of our readers are doubtless aware, a bill has been drawn by a commission consisting of Mr. Luther R. Marsh, Mr. Louis Fitzgerald, Mr. Waldo Hutchins, Mr. Charles L. Tiffany, Mr. William W. Niles, Mr. George W. McLean, Mr. Thomas J. Crombie, and Mr. John Mullaly, which provides for the laying out of a number of additional parks in the upper part of the city. The bill has passed both branches of the Legislature, and needs only the Governor's signature to become a law. In view of the disinterested devotion to the welfare of the State, and of the various portions of the same, which Governor Cleveland has shown during his term of office, we feel confident of his approval of the bill. To urge the hygienic grounds on which some such provision for additional parks should be made for New York appears superfluous, so far as our readers are concerned, for few propositions are less disputable than that the health of a city population is vastly promoted by the number and size of its open areas. The proportion of the extent of our present parks to the population is ridiculously small when compared with what is found in other cities, as is shown by the following table, which is included in the report of the commission to the Legislature:

	Population.	Acres in parks.	Inhabitants to the acre.
New York	1,500,000	1,094	1,363
London	4,500,000	22,000	205
Paris	2,250,000	172,000	13
Vienna	800,000	8,000	100
Berlin	1,174,293	5,000	235
Dublin	366,000	2,000	183
Brussels	350,000	1,000	350
Amsterdam	350,000	800	437
Tokio	1,000,000	6,000	167
Philadelphia	900,000	3,000	300
Chicago	650,000	3,000	200
Washington	150,000	1,000	150
St. Louis	350,000	2,100	167
Boston	400,000	2,100	190
Brooklyn	600,000	940	629
Buffalo	160,000	620	258
Savannah	33,000	60	550
Baltimore	400,000	776½	515
San Francisco	250,000	1,181	211

It is well known that in general the death-rate of New York exceeds that of almost every other large American town, as well as those of most large cities in the civilized world. While there is abundant reason to think, as we have stated on former occasions, that the reported death-rate of New York is explicable by circumstances not generally taken into account, the legitimate tendency of which is to mitigate the stigma attaching to the city by reason of its mortality bills, yet this fact should not diminish our efforts to do away with the nominal death-rate shown by the figures. Nothing should be left

undone to accomplish the purpose; least of all can we afford to neglect so obvious a measure as the providing of more "breathing spaces" for the multitudes now crowded into our tenement-houses. There is no denying that the need in this respect is at present most pressing in the older parts of the town, where, as things are now, children have to be carried a mile or more in many instances before a park is reached—a park for show rather than for use, save for the tramps that monopolize the benches; where for an infant to roll on the grass is looked upon as sacrilege. This, we admit, is true; but, because we have committed one grievous wrong, must we go on in that course to the end of the chapter? To establish parks in the lower part of the city must be the work of time, but the opportunity is offered now to redeem our errors in great measure by opening parks in the district recently annexed to the city, since, as we understand, it can be done at an outlay that appears insignificant in comparison with other than the sanitary advantages to be derived.

We trust that it will not become a question which of the proposed new parks can best be dispensed with; we need them all. In some respects the Pelham Bay Park seems most desirable, both on account of its extensive frontage on the sound and by reason of its accessibility when the railways now in prospect are completed. But we hope to see the plan elaborated by the commissioners and sanctioned by the Legislature approved of by the Governor.

NEWS ITEMS, ETC.

INFECTIOUS DISEASES IN NEW YORK.—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending May 27, 1884:

DISEASES.	Week ending May 20.		Week ending May 27.	
	Cases.	Deaths.	Cases.	Deaths.
Typhus	4	3	1	1
Typhoid Fever	4	1	7	2
Scarlet Fever	99	15	76	17
Cerebro-spinal meningitis. . .	6	4	3	3
Measles	94	13	103	21
Diphtheria	30	17	47	23

SMALL-POX IN LONDON.—The London medical journals of the 17th inst. report that on the preceding Saturday it was stated at a meeting of the Metropolitan Asylums Board that no fewer than 346 new cases of the disease had been received by the asylum authorities during the fortnight ending on that date. They came mostly from the eastern parts of the metropolis.

SMALL-POX AT QUARANTINE.—The steamship Polaria, which arrived at this port toward the close of last week from Hamburg, was detained at the quarantine station, having been found to have five persons on board sick with small-pox. The patients were removed to the Riverside Hospital. Three new cases are said to have broken out on board the ship since her arrival.

THE BOYLSTON PRIZES.—The questions proposed for the year 1885 are the following: 1. The Alleged Recent Reappearance of Intermittent Fever in New England; its History and the Pathology of the Disease—prize, \$250. 2. The Best Preliminary Education for the Study of Medicine—prize, \$200. The questions proposed for the year 1886 are: 1. The Influence of the Soil as a Factor in the Causation and Spread of Typhoid Fever—prize, \$350. 2. The Relation of Hospitals to Medical Educa-

tion—prize, \$200. The essays should be sent in before the first Wednesday in April of each year. Further information may be had of Dr. W. F. Whitney, Harvard Medical School, Boston.

A BILL TO REMUNERATE ARMY NURSES has been introduced into the United States Senate, providing that female nurses who served in the army during the late civil war shall be paid such sums as shall make the amounts received by them equal to \$25 a month for the time of their service as nurses.

QUACKERY IN IOWA.—At the recent annual meeting of the Iowa State Medical Society, the President, Dr. Robinson, called attention in his address to the necessity of securing an improved legal regulation of the practice of medicine. Legislation by neighboring States, he said, had driven great numbers of quacks into Iowa.

CREMATION seems to be making its way in Pennsylvania, in spite of the opposition which it has had to encounter. A Philadelphia correspondent of the "Tribune" states that a new crematory is to be built near that city, and that Dr. Joseph Leidy, who had been reported to be opposed to cremation, has published a statement disclaiming that feeling, and expressing his gratification that the late Dr. Gross directed his remains to be incinerated.

A BILL CREATING A NEW YORK STATE BOARD OF PHARMACY, and prescribing regulations for the practice of pharmacy in all the counties except New York, Kings, and Erie, has been signed by the Governor.

CONTAGIOUS PLEURO-PNEUMONIA is reported to have been detected in a number of stables in Blissville, Long Island, by an inspector acting under the State Board of Health. It is said that the cows are improperly cared for, and are milked up to the time of becoming moribund, the milk being served to customers, or are slaughtered and the meat sent to market. It is to be hoped that the board will take energetic measures in these cases.

"ROUGH ON RATS," the deadly effects of which upon human beings we have had frequent occasion to record of late, was employed successfully by a suicide in this city last Sunday. Is it not about time for some measures to be taken to check its indiscriminate sale?

SUDDEN DEATH OF A PHYSICIAN.—Dr. B. H. R. Davenport, of Nanticoke, Pa., is reported to have fallen dead recently while engaged in dressing a wound.

ARMY INTELLIGENCE.—*Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from May 18, 1884, to May 24, 1884:*

WILSON, GEORGE F., First Lieutenant and Assistant Surgeon. Ordered to proceed to Fort Canby, Washington Territory, for temporary duty at that post, relieving Assistant Surgeon W. O. Owen, Jr., U. S. A., who will report in person at these headquarters for further orders. Par. 5, S. O. 62, Headquarters Department of the Columbia, May 12, 1884.

STERNBERG, GEORGE M., Major and Surgeon. Relieved from duty in the Department of the East and ordered to report to the Surgeon-General of the Army for temporary duty. Par. 2, S. O. 115, A. G. O., May 17, 1884.

MAGRUDER, DAVID L., Lieutenant-Colonel and Surgeon. Ordered to be relieved from duty as medical director, Department of the Missouri, and to proceed to Philadelphia, Pa., and assume duties of attending surgeon and examiner of recruits in that city.

FRYER, BLENOWE E., Major and Surgeon. Ordered from Department of the Missouri to Department of Dakota.

EWEN, CLARENCE, Captain and Assistant Surgeon. Ordered from Department of the Missouri to Department of the Platte.

STRONG, NORTON, First Lieutenant and Assistant Surgeon. Ordered from Department of the Platte to Department of the Missouri. Par. 7, S. O. 115, A. G. O., May 17, 1884.

NAVAL INTELLIGENCE.—*Official List of Changes in the Medical Corps of the Navy during the Week ending May 24, 1884:*

MARTIN, W., Assistant Surgeon. Ordered to U. S. Constellation.

NELSON, H. C., Medical Inspector. Granted leave of absence for one year.

BALDWIN, L. B., Passed Assistant Surgeon. Detached from U. S. S. Pensacola, and waiting orders.

WELLS, H. M., Surgeon. Ordered to Naval Hospital, Brooklyn.

MURRAY, J. M., Passed Assistant Surgeon. Detached from U. S. S. Minnesota and ordered to U. S. S. Passaic.

WAGGENER, J. R., Passed Assistant Surgeon. Ordered to U. S. S. Hartford.

SOCIETY MEETINGS FOR THE COMING WEEK.—*Monday, June 2d:* New York Academy of Sciences (Section in Biology); Medico-Chirurgical Society of German Physicians; Morrisania Medical Society (private); Brooklyn Anatomical and Surgical Society (private); Utica, N. Y., Medical Library Association.

Tuesday, June 3d: New York Obstetrical Society (private); New York Neurological Society; Medical Societies of the Counties of Columbia (semi-annual), Franklin, Herkimer (annual), Niagara (annual), Orange (annual), Saratoga (annual), Schoharie (annual), Ulster (annual), and Yates (annual), N. Y., and Hudson and Warren, N. J.; Buffalo Medical and Surgical Association; Elmira, N. Y., Academy of Medicine; Ogdensburg, N. Y., Medical Association.

Wednesday, June 4th: New Hampshire Medical Society (Concord); Medical Societies of the Counties of Cattaraugus (annual) and Richmond, N. Y.

Thursday, June 5th: New York Academy of Medicine; Society of Physicians of the Village of Canandaigua, N. Y.

Friday, June 6th: Practitioners' Society.

OBITUARY NOTES.

DR. JAMES MILLAR, OF NORTH PROVIDENCE, R. I.—Dr. Millar, one of the oldest members of the medical profession in the State of Rhode Island, died May 15th, at the age of seventy-eight. Born in Scotland, and educated at Glasgow, he came to Providence at an early age, and devoted a long and useful life to the practice of medicine, respected and beloved by all with whom he had to do. He was the father of Dr. Robert Millar, an eminent surgeon of Providence.

Proceedings of Societies.

BROOKLYN PATHOLOGICAL SOCIETY.

Meeting of April 10, 1884.

The President, Dr. B. F. WESTBROOK, in the chair; Dr. LEFF, Secretary.

ANGIOMA OF THE COCCYX.—Dr. F. A. JEWETT presented a specimen, and gave the following history:

"The accompanying tumor was removed in January, 1884, from the coccyx of Miss B., aged thirty-eight, who presents the following history:

"At birth her mother says it was as large as a foetal head, and of a globular form. It decreased in size, becoming firmer, up to her seventh or eighth year, when it was of about the size of a goose's egg, and quite hard. When about seventeen years of age she had a fall, striking heavily upon the tumor. An abscess resulted from this, but healed without giving her much trouble. Three years ago she fell again, striking the tumor a sharp blow upon the edge of a door-sill, an abscess following, which continued to discharge three or four ounces of offensive pus daily, until the removal of the tumor in January. Shortly after her second fall she went under the care of a quack, who injected it with a caustic solution. After pursuing his treatment for a year she yielded to the advice of physicians in this city and consented to its removal, which was accordingly done, and the patient made a good recovery."

CARCINOMA OF THE LIVER.—Dr. GEORGE DRURY presented a case, with the following history:

"Elizabeth N., aged forty-six; married; English. The patient had always enjoyed good health, with the exception of an occasional attack of biliousness. Last August, after nursing her daughter through a prolonged typhoid fever, she was taken with what she supposed to be one of her usual bilious attacks; but, instead of obtaining relief, her symptoms continued, and she noticed she was developing a jaundiced appearance, that her urine was of a dark-brown color, that her gastric symptoms, such as nausea, vomiting, pyrosis, and flatulence, were increasing in severity. She complained of no pain referable to the stomach or liver, but vomited matter consisting of food taken, mixed with a small quantity of mucus. She was at this time treated for gastro-duodenal catarrh, with little alleviation of her symptoms, and was rapidly emaciating, losing strength, and becoming despondent. I saw the patient about November 1, 1883, and elicited the foregoing history. The physical examination of the liver revealed a marked prominence of the right hypochondriac, including in part the epigastric and right lumbar regions. The notch of the liver could be felt about half an inch above and to the right of the umbilicus. The anterior border of the right lobe could be traced downward and to the right, reaching within an inch of the crest of the ilium. The surface of the liver was hard and nodular, and markedly so at the notch, where a hard nodule, of about the size of a walnut, could be felt. This last-named condition was pointed out to me by Dr. B. F. Westbrook, who examined the patient about November 22d. On December 1st she vomited two ounces of dark blood. Four days later she had a hæmorrhage from the bowels, amounting to about four ounces of bright-red blood, which was repeated with each stool, but in smaller quantities, for four days. The gastric symptoms previous to the hæmatemesis had greatly improved under treatment, so that she was able to retain milk and broths without vomiting, but after the hæmorrhage her gastric irritability returned with greater severity. She had not at any time complained of pain over the liver, nor had she any tenderness on examination. Up to January 1st there was no evidence of ascites, but on January 8th, one week later, I called to see Mrs. N., and found her abdomen much distended and filled with fluid up to the umbilicus, and her feet and ankles oedematous. The oedema and ascites daily increased, interfering with the action of the heart and with respiration. On February 2d the hæmorrhage from the bowels returned, and continued with each evacuation up to February 13th, when she died from exhaustion.

"Autopsy, held twenty-four hours after death, by Dr. J. W. Brandt, in the presence of Dr. M. Gay and myself.—Body greatly emaciated, abdomen distended, lower extremities oedematous, skin jaundiced, cranial and thoracic organs not examined. On making an incision through the abdominal walls, a

large quantity of amber-colored fluid escaped. The liver stood out prominently, measuring about four inches below the margin of the right ribs. The gall-bladder was much distended and presented at the notch, extending an inch from its border; the surface of the liver was studded with isolated nodules of irregular size. The liver, though much enlarged, was not altered in shape. The right lobe was found to be more extensively diseased than the left. A cicatrix-like depression was found on the convex surface of the right lobe. A cancerous deposit was found to exist on the walls of the gall-bladder. An incision being made into the liver, the cut surface presented a yellowish appearance, and dark-brown juice oozed from the bile-ducts on pressure. There was enlargement of a few mesenteric glands, all the other abdominal organs being healthy.

"The points of interest in this case are the following: The early appearance of jaundice, due to the disease being primarily located around the larger bile-ducts, associated with a more or less catarrhal condition of their mucous membrane, obliterating the caliber of the ducts, thus preventing the secretion of bile, and in return producing absorption of the bile products, giving the early symptom of jaundice. Secondly, the absence of pain and tenderness during physical examination is of interest, for in cases of hepatic cancer, where the liver is not enlarged and is concealed under the costal arch, the persistent tenderness of the liver induced by percussion of the hepatic region, where there is absence of any cause of an existing cachexia, becomes a highly diagnostic sign. Thirdly, the late appearance of ascites, showing that the disease did not interfere with the portal circulation until it had become far advanced. Lastly, the escape of all the other organs from cancerous deposits, as shown by the pancreas, which has been removed with the liver, and apparently is in a normal condition. Dr. L. F. Criado has kindly prepared two microscopical sections from this specimen, which are present for exhibition."

BRONCHOCELE.—Dr. F. W. ROCKWELL showed a thyroid gland that he had removed from a patient in St. Mary's Hospital, and read a paper on the operation. [See p. 608.]

H. N. READ, M.D., *Editor for the Society.*

ILLINOIS STATE MEDICAL SOCIETY.

Thirty-fourth Annual Meeting, held in Chicago Tuesday, Wednesday, and Thursday, May 20, 21, and 22, 1884.

Tuesday—First Day.

The meeting was called to order by the President, Dr. EDMUND ANDREWS, of Chicago, and a prayer was offered by the Rev. ABBOTT E. KITTEDGE.

THE ADDRESS OF WELCOME was read by Dr. E. INGALS, of the Committee of Arrangements.

GENERAL SHERMAN was then introduced, and in a few remarks expressed his pleasure at meeting the medical profession of the State in Chicago.

THE ORDER OF BUSINESS was announced by the Chairman of the Committee of Arrangements, Dr. D. W. Graham, as follows: Reports of the committees on practical medicine, surgery, obstetrics, gynecology, ophthalmology and otology, drugs and medicines, and necrology; volunteered papers. Dr. Graham also announced the invitations that had been extended to the delegates.

THE PRESIDENT'S ADDRESS was then read. It contained some recommendations as to minor changes in the rules of procedure, and touched upon the subject of ethics. All codes of ethics were necessarily imperfect; what was needed was not so much an improvement of the code, however, as a better com-

prehension of the general principles that underlay all written codes. Etiquette was a different matter, being more or less artificial and the product of the particular state of culture in the community affected. Those who confounded etiquette with ethics committed a grave blunder, and might be enlightened if it were possible to take them back forty or fifty years, to the period which preceded the formation of the American Medical Association, when there was no code; they would then see what had been accomplished by the code. At the conclusion of the address, a vote of thanks to the President was passed.

THE REPORT ON PRACTICAL MEDICINE, by Dr. J. C. FRYE, of Peoria, was read by Dr. McIlvaine, of Peoria. It dealt with the germ theory of disease, and detailed many of the advances in pathology, diagnosis, and therapeutics that had taken place during the year.

Afternoon Session.

URANOPLASTY was the subject of remarks by Dr. PRINCE, who showed a patient on whom he had performed the operation for cleft palate with success.

RECENT ADVANCES IN SURGERY was the subject of a paper by Dr. ROSWELL PARK, of Buffalo, N. Y., formerly of Chicago, in which an interesting exposition was given of the present state of antiseptic surgery, and new operative procedures were discussed.

GUNSHOT WOUNDS were the chief theme of a paper by Dr. DAVID S. BOOTH, of Sparta, who gave an account of a case of extensive gunshot injury of the neck and shoulder.

THE GERM THEORY OF DISEASE, in its practical bearings, was treated of in a paper by Dr. HENRY GRADLE, of Chicago. Particular reference was had to the cholera germ and to the bacillus of tuberculosis.

ALKALOIDAL AND KINDRED MEDICATION was the title of a paper by Dr. J. A. ROBISON, of Chicago, which was a vigorous plea in favor of precision in pharmacy and prescribing.

PLASTIC OPERATIONS IN GYNÆCOLOGY were the subject of a short paper by Dr. L. H. COER, of the Committee on Gynæcology.

Wednesday—Second Day.

THE COMMITTEE ON NECROLOGY reported at the morning session, through its chairman, Dr. E. INGALS, giving an abstract of the mortality among the physicians of the State for the years 1882 and 1883. Of seventy-eight physicians whose deaths had been reported, the average age was fifty-two years, a showing which the committee thought ought to be improved. The report concluded with short obituary sketches of Dr. JOSEPH OSMOND HAMILTON, of Jerseyville, and Dr. C. E. PARKER, of Beardstown.

EXCISIONS OF JOINTS were treated of in a paper by Dr. CHRISTIAN FENGER, with special reference to the final results in successful excisions of the knee and the hip. These results were illustrated by the exhibition of patients whom the reader had had under treatment.

VACCINATION.—Dr. M. F. BASSETT, of Quincy, read a paper in which he took the ground that humanized virus had been shown by long experience to be preferable to bovine virus. For his part, he preferred that those of his patients who refused to be vaccinated with the former should bear the responsibility themselves, for he would not use the animal virus.

Dr. LYMAN called attention to the speedier action of the humanized virus.

Dr. INGALS had never perceived any great difference between the two kinds of virus, provided they were good of their kind. Much depended on the way in which they were used.

Dr. E. P. COOK agreed with Dr. Ingals, and deprecated Dr. Bassett's position.

Dr. A. B. STRONG, of Chicago, said that, in a long experi-

ence, he had never observed that bovine virus acted more violently than the humanized variety.

Dr. COCHRAN, of Greenfield, was opposed to the use of humanized vaccine, on account of the danger of communicating syphilis.

Dr. JOHNSON, of Chicago, had studied the statistics of forty thousand vaccinations with humanized virus, done in the epidemic that succeeded the great fire in Chicago, and had not met with a single instance of the conveyance of any constitutional taint in the operation. There was a great deal in the art of vaccination; if properly performed, the operation was always beneficial.

The discussion was further continued by Dr. GILL, of Cleveland, Dr. S. J. JONES, and Dr. ANDREWS.

Afternoon Session.

BILATERAL PARALYSIS OF THE ABDUCTORS OF THE VOCAL CORDS was the title of a paper by Dr. H. A. JOHNSON, of Chicago, who laid stress on the limitation of the dyspnoea to inspiration. In illustration of the subject, a patient was shown on whom Dr. Edward Andrews had performed tracheotomy in 1881.

Dr. GRAHAM showed a patient on whom he had done the operation four weeks before. In that case the Durham and other fenestrated tubes could not to be used, and the speaker had devised one for the purpose.

MEMBERS BY INVITATION were announced by the Committee of Arrangements as follows: Dr. A. J. STONE, of St. Paul; Dr. C. J. PITNEY, of Jacksonville; Dr. R. F. DWYER, of Ottawa; Dr. G. W. JONES, of Danville; Dr. FRANK ANTHONY, of Sterling; Dr. E. R. WILLARD, of Wilmington; Dr. K. E. RICH, of Winona; Dr. C. A. PALMER, of Princeton; Dr. W. A. BYRD, of Quincy; and Dr. R. M. WILSON, of Lincoln.

THE TREATMENT OF DIPHTHERIA formed the chief theme of a paper read by Dr. J. P. MATTHEWS, of the Committee on Diseases of Children. After touching upon the modes of origin of the infectious diseases in general, the reader sketched his method of treating diphtheria, consisting largely of inhalations. The subject of the dietetics of infancy was also considered.

Dr. K. E. RICH, of Winona, accepted the germ theory, as did Dr. WHITMEYER, of Metamora. The latter had used chloride of lime, given in the form of spray, with benefit.

Dr. HAMILI, of Chicago, spoke highly of the efficiency of guaiacum.

In view of the favor with which the germ theory was received, Dr. DAVIS, of Chicago, asked what the effect would be of large doses of corrosive sublimate, which was now the favorite germicide.

Dr. E. P. COOK, of Mendota, had had a limited experience with the remedy, and had found that, while patients with follicular pharyngitis recovered, those with malignant diphtheria all died.

PHYSIOLOGY was the subject of a paper by Dr. A. WETMORE, of Waterloo. Dr. J. F. TODD, of Chicago, read the REPORT OF THE COMMITTEE ON ORIGINAL INVESTIGATION. Dr. F. C. SCHAEFFER read a paper ON FRACTURE OF THE GREATER TUBEROSITY OF THE HUMERUS.

Thursday—Third Day.

At the morning session the COMMITTEE ON MEDICAL LEGISLATION FOR THE INSANE reported progress, and was continued, for the purpose of presenting certain suggestions to the next Legislature.

The subject of the SUPPLY OF ANATOMICAL MATERIAL was brought up by Dr. A. B. STRONG, of Chicago, who spoke of the defective provision made by the laws of the State for that purpose. He asked for the co-operation of the profession through-

out the State in endeavoring to secure more satisfactory legislation in regard to the subject.

OFFICERS FOR THE ENSUING YEAR.—The nominating committee reported the following list of nominations, which was confirmed by vote of the society: President, Dr. DANIEL S. BOOTH, of Sparta; Vice-Presidents, Dr. S. C. PLUMMER, of Rock Island, and Dr. W. T. KIRK, of Atlanta; Treasurer, Dr. WALTER HAY, of Chicago; Secretary, Dr. S. J. JONES, of Chicago; Assistant Secretary, Dr. H. B. BUCH, of Springfield.

A REPORT ON THERAPEUTICS was read by Dr. RANSOM, of Rockford, who called particular attention to the diuretic properties of the *Euphorbia corollata*.

THE REPORT ON OBSTETRICS was read in abstract by Dr. H. K. CRAWFORD, of Monmouth, a member of the committee.

Afternoon Session.

Various reports were read and cases related, mostly bearing on obstetrics and gynecology, after which Dr. R. TILLEY, of Chicago, read a paper on the JEQUIRY BEAN AND ITS USE IN PANNUS.

SIMPLE RENAL CATAREH.—A report on this subject was to have been presented by Dr. I. N. DANFORTH, of the committee appointed for the purpose, but, the paper not being ready, the committee was continued for another year.

DRUGS AND MEDICINES was the title of a paper by Dr. B. F. CRAMMER, of Warren, who recommended that physicians should put up their own prescriptions.

MYOPIA.—A paper on this subject, by Dr. F. C. HOTZ, was read in abstract.

POTT'S DISEASE.—Dr. C. E. WEBSTER, of Chicago, read a paper on this affection.

PANCREATIC ANÆMIA was the title of a paper by Dr. C. W. EARLE, of Chicago, who related four cases.

MASTOID ABSCESS was considered in a paper by Dr. E. L. HOLMES, of Chicago.

PURULENT INFLAMMATION OF THE MIDDLE EAR was the title of a paper by Dr. H. GRADLE.

PRIZES.—On motion of Dr. WALTER HAY, it was voted to offer a prize of \$100 for the best essay on the treatment of diphtheria, and another of the same amount for the best tabulated statement of ten cases of any disease coming under the care of any one practitioner.

After voting to hold the next meeting in Springfield, the society adjourned.

NEW YORK OBSTETRICAL SOCIETY.

A STATED meeting was held December 18, 1883, Dr. W. M. POLK, President, in the chair.

LARGE INTRA-UTERINE MYOMA REMOVED BY LAPAROTOMY.—

Dr. J. B. HUNTER related the following case: A woman, thirty-four years of age, came to him with an abdominal tumor which her physician had pronounced ovarian. It had first been noticed eight months before, and had grown rapidly, having reached about the size of a child's head. It seemed too hard for an ovarian tumor and too soft for a fibroid. The patient, who was unmarried, had always had scanty menses until since the appearance of the tumor, when the flow increased in quantity at the regular periods, and there was some flow during the intervals. Several of the surgeons of the Woman's Hospital examined her, and opinions were divided between a fibro-cyst, an extra-uterine fibroid, and an ovarian tumor. Laparotomy was performed on Saturday, December 15th, and, after a free incision had been made, a large tumor, believed to be a fibroid, was encountered. Several turns of an elastic ligature were thrown around the neck of the entire mass, and an incision was made, when it was

found that the mass was composed of the uterus greatly enlarged by the presence of a tumor within. The tumor was enucleated and withdrawn through an incision made into the uterus. A clamp was then put well down on the uterus, which was cut away and the abdominal wound closed around the pedicle. The patient had since done well. The tumor had not yet been examined by the pathologist. It contained a considerable amount of bloody fluid in cavities, but not a sufficient amount to give distinct fluctuation. The elastic ligature controlled hæmorrhage perfectly. Before the operation the probe had been passed into the uterus a distance of four inches, but could not be swept around.

Dr. G. T. HARRISON thought there could be no question but that the proper method of removing such a tumor was by laparotomy; the principal question which could arise was with regard to the method of treating the stump.

Dr. H. T. HANKS asked whether, had the exact nature and condition of the tumor been recognized, it would have been worth while to try treatment by ergot.

Dr. H. J. GARRIGUES did not think that ergot would cause a tumor of such large size to disappear.

A TRACHELORRHAPHY NEEDLE.—Dr. HANKS presented a needle for repairing the cervix. It possessed the advantage over that in ordinary use of having the concave side rounded and the convex angular, rendering it stronger and more suitable for introduction through cicatrized tissue. The smallest portion of the shaft was at the eye, thus admitting of easy passage of the needle when once the point had been passed and seized with the needle-holder.

Dr. HUNTER and Dr. BACHE McE. EMMET had used a needle answering to the description given by Dr. Hanks with advantage; it was probably the same needle.

CERVICAL MYOMA COMPLICATING PREGNANCY.—Dr. HARRISON had been called to see a woman, thirty-four years of age, who had been married eleven months. During the first five or six months of menstrual life the flow had been regular; it then became irregular, and during the last few years she had suffered from lumbar and pelvic pain and difficulty in urination. The pain grew in intensity. She was under the impression that she was pregnant, as during the past two months menstruation had been absent. On examination, an abortion was found to be in progress, and a large mass was felt in the vagina, the os uteri lying behind. The os was crescentic and distorted to the left. The ovum was expressed. After two months the tumor was removed by means of the scissors and the vulsella. Considerable hæmorrhage took place. Had pregnancy gone to full term, it was probable a good deal of difficulty would have been experienced in expelling the fetus.

SUPRAPERITONEAL MYOMA REMOVED BY LAPAROTOMY.—Dr. HARRISON also related this case, which was specially of interest from a diagnostic point of view. The patient was first seen by him eighteen months ago, at which time he could discover no neoplasm. In June last, however, he found a large mass filling Douglas's cul-de-sac, encroaching upon the rectum, and pushing the uterus forward against the pubes. It simulated an hæmatocèle, but the history did not correspond; the patient had only suffered a short time from obscure pain. Afterward she was unable to pass water, and it was necessary to use the catheter. The tumor increased in size rather than diminished. He then diagnosed ovarian tumor, and, as it was rapidly increasing in size, advised an early operation. Dr. Thomas coincided in the diagnosis and the necessity for an operation. At the operation the tumor was found to be a myoma, springing from the posterior face of the fundus uteri, and completely occupying the posterior cul-de-sac. Great difficulty was experienced in extracting the tumor from its wedged position in the pelvic cavity,

although it had no adhesions. The abdominal wound had to be reopened the next day in order better to secure the pedicle. The patient died of septicæmia and peritonitis.

Dr. BAGGE McE. EMMET referred to a case similar to the first one related by Dr. Harrison, in which he refused to remove the tumor, which was of large size and situated in front of the cervix, at the utero-vesical junction on the anterior lip of the cervix, through fear of leaving a large cavity and of subjecting the patient to the risk of septicæmia. The late Dr. Peaslee also refused to operate in the case.

Dr. HANKS said that he once removed a fibroid tumor from the posterior wall of the cervix, of about the size of the one presented by Dr. Harrison, and the pain and distress referred to it before its removal were very marked in that instance, being greater than in cases of tumor situated in the walls of the body of the uterus.

The PRESIDENT referred to a case similar to the second one related by Dr. Harrison, which illustrated the impossibility of lifting the tumor out of the pelvis. Before he got ready to remove the tumor the patient died of dysentery, which was apparently due to pressure of the growth upon the rectum. At the autopsy the adhesions were found to be so extensive that any forcible attempt at reduction would necessarily have resulted in tearing out nearly the whole pelvic viscera.

UTERINE FIBROID; INVERSION OF THE UTERUS; DIFFICULTY OF DIAGNOSIS.—Dr. ROBERT WATTS related the case of a woman who entered the Roosevelt Hospital with the history that for several months she had been losing a good deal of blood at irregular intervals, and that recently hæmorrhage had been quite profuse. On introducing the finger into the vagina, a tumor resembling a mushroom was encountered, the lower portion being rounded and the upper portion presenting a distinct shoulder. After the patient's condition had been improved, ether was administered, and a thorough examination was made *per rectum* and *per vaginam*, when it was easily determined that the uterus was inverted and a tumor was attached to the inner surface of the fundus. After apparently enucleating the tumor, reduction was attempted, but unsuccessfully. It was then found that only the shell covering the tumor had been removed. The entire growth was now easily enucleated and the uterus reduced without difficulty.

Dr. HARRISON spoke of the difficulty of diagnosis in these cases, and of limiting the operation to the growth itself. The late Professor Spiegelberg found, after supposed ablation of the tumor in a certain case, that he had taken away the fundus of the inverted uterus.

Dr. CLEMENT CLEVELAND believed it was maintained that this accident could not happen if the spoon-saw was used.

The PRESIDENT related a case which he had seen several years before, in which the cause of inversion—namely, the presence of a submucous fibroid tumor—was not recognized until after death. The patient was rachitic, and had a deformed pelvis. The vaginal tumor presented the exact appearance of an inverted and slightly enlarged uterus; not the least irregularity could be detected on its surface. This was a point which had been noticed by several physicians who saw the case in consultation. All attempts at replacement failed. The patient died of exhaustion, and at the post mortem the submucous fibroid was recognized. He believed that the only way in which the tumor could have been recognized during life would have been by microscopical examination, but even this might have failed.

LOCAL TREATMENT OF DIPHTHERIA BY BICHLORIDE OF MERCURY.—Dr. HANKS said that he had for two years been employing minute doses of corrosive sublimate internally in the treatment of diphtheria in children, and believed that he had obtained better results thereby than by the use of any other medicine.

But about two weeks ago he saw a child in whom the palate and tonsils had been completely covered with the diphtheritic exudation for two days previous. He administered corrosive sublimate, in one-one-hundred-and-sixtieth-grain doses, in a teaspoonful of water, every two hours, together with Hoffmann's anodyne in doses of one third of a drachm. He considered the child convalescent on the seventh day, but was sent for again on the tenth, and found the tonsils again covered with the membranous exudation. He then had the fauces sprayed every half hour by the hand atomizer, using a solution containing two grains of bichloride of mercury, one ounce of glycerin, and seven ounces of rose-water. The membrane entirely disappeared in the course of twelve hours. In another similar case, except that there had been no relapse, the bichloride spray produced the same result, the former internal treatment having failed. With the disappearance of the membrane, the patients went on to convalescence. He believed that the result was due to the local effect of the agent employed. He was in the habit of using fumigation with sulphur, also the other well-known methods of keeping the air in the sick-room free from the poison.

HENRY J. GARRIGUES, M.D.,

B. F. DAWSON, M.D.,

FRANK P. FOSTER, M.D., *ex officio*,
Committee on Publication.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Meeting of April 28, 1884.

The President, Dr. S. O. VAN DER POEL, in the chair.

THE PRESIDENT announced the death of Dr. Willard Parker, Sr., and, after some eulogistic remarks, said he would shortly appoint a memorialist. Dr. GARRISH moved that a committee of three be appointed to draft resolutions of condolence, to be sent to the family. Carried.

TRACHOMA, AND THE ETIOLOGY OF JEQUIRITY OPHTHALMIA.—Dr. JOSEPH A. ANDREWS then read a paper which he said there were two reasons for, the first being the fact of the introduction of a new therapeutic agent for the treatment of trachoma, and the second the new view of the etiology of jequirity ophthalmia advanced by Professor Sattler. The remarks upon trachoma were based upon the examination of eighteen healthy human conjunctivæ and forty cases of trachoma, while those upon the etiology of jequirity ophthalmia were based upon experiments upon a large number of dogs and rabbits and upon the examination of thirty-seven cases of trachoma with this end in view. Sattler professed to have discovered a micrococcus in the tissues which was the cause of the ophthalmia, but, while Dr. Andrews was convinced, from numerous examinations of blennorrhœal and trachomatous pus, that micrococci were constantly present, he had not been able to demonstrate their etiological relation to the disease; he had been unable to isolate a micrococcus, or any other variety of micro-organism, which was capable of producing it. He still thought it probable, however, that a micro-organism might be an important factor in the etiology, but he thought it should be sought for in the secretions rather than in the tissues. He then considered the influence of climate, sex, diathesis, and hygienic conditions in the production of trachoma, and stated that he believed the most important factor was bad hygiene. Trachoma was comparatively rare in those whose means permitted them to live well hygienically and in healthful climates. In southern Russia trachoma constituted thirty-five per cent. of all eye diseases, and this large percentage he thought could be traced to the small, filthy homes of the people. In New York and Brooklyn it constituted four and eight tenths per cent. of all ophthalmic cases.

The writer then considered the appearances in trachoma, his own observations being based upon the examination of fifty-six cases. In every case several of the prominences of the conjunctiva were excised, and in several instances the entire conjunctiva was examined after death. In all cases, at first, the epithelial surface was found smooth, not thickened, and the adenoid tissue was infiltrated with reticulated cells, the latter being not uniformly distributed. The tissue between the foci of infiltration might be quite normal, but in most cases it was slightly hyperemic. As a rule, at an early period he had noticed that the foci of infiltration had a round contour. The cells were glandular and closely packed together, but as yet there was no true anatomical boundary. He had never been able to find actual tubular glands in the human conjunctiva. He did not believe in the existence of special forms of the disease. In discussing the various points connected with the etiology and pathology of the disease, Dr. Andrews gave at some length the views entertained by different authors.

With regard to treatment, corrosive sublimate, on account of its astringent properties and its mechanical effect in removing the secretions, was useful in destroying bacterial growth and in preventing decomposition. Efforts heretofore had been directed to destroying the granulations by various means. He would not take time to enumerate all the means employed to combat and eradicate the disease, but would first speak only briefly of caustics. To destroy granulations their use might be correct enough, but they also destroyed parts which it was not desired to influence—in other words, when the granulations were destroyed likewise destroyed the conjunctiva. Caustics might yield good results in a few instances when employed with intelligence and prudence, but in the overwhelming majority of cases they had caused the patients a great deal of suffering, and finally brought about a condition which was even much worse than the original trouble. With the announcement of the discovery of a micro-organism in trachoma tissue, of course came the suggestion for the employment of a parasiticide, and corrosive sublimate was naturally seized upon. Sattler employed it in solution of one to twenty thousand in cases of granulations. He did not know whether he had used it in trachoma. The author had employed it in trachoma, and, even after he had come to the conclusion that there were no bacteria in trachoma tissue, he had continued to use it for its astringent and mechanical effects. When used in a solution of one quarter to one eighth of one per cent., it had considerable astringent effect. The solutions came away clear of micro-organisms, and were useful in cases exposed to filth. But the cases had to be watched very carefully, as even very weak solutions often produced a marked irritant effect upon the eyes.

Sulphate of copper in crystals was probably the most popular and generally employed agent in the treatment of granular conjunctivitis, but it was often used in a manner to aggravate the disease. Sulphate of copper, nitrate of silver, and subacetate of lead still preserved a conspicuous place in the treatment of trachoma, but they had to be used with much care and with intelligence. He had excised the cul-de-sac in three cases in which there was pronounced pannus corneae, the latter condition being favorably influenced by the operation. The whole of the cul-de-sac was excised without touching the tarsus.

The author then came to the subject of jequirity ophthalmia, and, after giving an account of the discovery of the use of jequirity in the treatment of affections of the eye, gave a summary of the results obtained with it in fifty-seven cases in his own practice. In only three of the number was it without result. Seventeen were partial cures, meaning by this that the granulations disappeared from the tarsal conjunctiva, but some

still remained in the cul-de-sac. In two of these cases subsequent treatment with nitrate of silver removed the granulations. In one instance the granulations disappeared from the tarsal conjunctiva, but remained in the cul-de-sac, and there was extensive ulceration of both corneae, a true diphtheritic inflammation with violent chemosis. The infusion here was used in the strength of five per cent., which, in view of the fact that the cornea in the first place was not affected, was entirely too strong. The patient was now, however, doing well except for impaired sight due to ulceration of the cornea centrally. In the remaining thirty-seven cases the result was complete cure, the granulations having disappeared from every part of the conjunctiva, the pannus, which had been very pronounced in the majority of cases, having disappeared, and the sight having improved in most cases from ability only to perceive light to vision equal to twenty one-hundredths, which was the best result so far obtained. These results showed that we had in jequirity a remedial agent of decided value, and, while it might not immediately destroy all the granulations, it diminished the pain and photophobia, and cleared the cornea. Jequirity ophthalmia differed from blennorrhoea in that the other eye could not be inoculated by the secretions from the affected one. After a single application of jequirity the phenomena developed slowly, the rapidity and the severity of the symptoms, however, varying with the strength of the solution. After eight hours the hyperæmia might be only slightly pronounced, but after twenty or thirty-six hours the eye presented a picture of pretty intense inflammation. The secretions were generally muco-purulent. On the third or fourth day the inflammation began to recede.

Dr. Andrews differed with Professor Sattler, who considered that jequirity ophthalmia was a bacterial disease, his reasons for differing with him being based upon certain experiments which he narrated.

Dr. T. R. POOLEY opened the discussion and limited his remarks chiefly to the treatment of chronic cases by jequirity. He had employed it in chronic cases among out-patients, and its effect had been almost *nil* when employed in weak solution; in greater strength it produced increased congestion and general signs of inflammation. He had reached the conclusion that it was a dangerous agent, and that it should not be used in any but marked cases in which other methods of treatment failed, and in which it was even justifiable to employ an agent that was liable to produce injury of the cornea. He had observed a number of cases in which it was being employed in two hospitals in Germany, and it was his opinion that the patients were receiving injury rather than good from the treatment. Diphtheritic inflammation of the conjunctiva could be produced by a strong caustic, by inoculation with pus, and also by jequirity. So far was he from thinking that in the latter agent we had a remedy of great and wonderful value, that he thought it would soon find its position with treatment by purulent inoculation, which had quite or very nearly gone into disrepute.

Dr. H. KNAPP thought that climate probably had more to do with the production of trachoma than other conditions, not excepting filth. The disease seemed more commonly to take its origin in low regions. With regard to jequirity as a therapeutic agent, he had used it in all kinds of trachoma in several hundred cases in dispensary patients. In about one-third-of-one-per-cent. solution it produced a mucous or muco-purulent discharge, but no marked therapeutic effect. A five-per-cent. solution, freshly made, invariably produced a croupous conjunctivitis. The result was, in the majority of cases, not only good, but brilliant, and he made parallel experiments, using this solution in one eye and copper in the other. The treatment with jequirity produced much quicker results than that with copper; but the latter agent, although it produced a slower change,

finally brought about recovery and caused less cicatricial tissue. In a few cases with jequirity treatment recovery could be said to be perfect, and that in a very short time. But, unfortunately, in one case purulent ophthalmia developed in one eye, which was also transmitted to the other eye, and both corneae were perforated. The child escaped, however, without very much affection of vision. The results of a three-per-cent. solution were excellent up to a certain point in some of the cases; but in two cases a single application had given rise to as severe a diphtheritic inflammation as he had ever witnessed. The cornea of one eye, in the first case, was perforated by the inflammatory process. In both cases the disease was transmitted to the other eye. Great care and cleanliness had been exercised in making the application. These cases had shaken his faith in the innoxiousness of the remedy, and it certainly was not uniform and entirely controllable. He would hesitate at present to employ it in any other class of cases than those in which other means had failed, and sight was very nearly destroyed.

Dr. E. GRUENING said the cases for which it was originally intended that jequirity should be used were limited to the severer forms—as inveterate pannus—and the solution employed was weak; but gentlemen had come to use strong solutions and in all sorts of cases, and he thought it was for that reason that it had come to be looked upon with less favor. He still believed that, in proper strength, used in hospital practice night and day for five days, prepared fresh, and employed in proper cases, the remedy was safe and efficacious. He himself had employed a five-per-cent. solution in two cases, and produced a diphtheritic inflammation. No bad result, however, had followed. In all the other cases, thirty-six in number, in which a weaker solution was employed, partial or total pannus being present, benefit had resulted.

Dr. R. C. BRANDEIS had once tried a three-per-cent. solution of jequirity in the treatment of an obstinate case of *ozæna*, taking special pains to limit the application to the desired point in the pharynx, and in the night he was called to see the patient in great haste, as he was said to be dying. He found the air-passages almost completely blocked by oedematous swelling of the mucous membrane which the solution had given rise to, and saved his patient only by scarification. The man recovered from the induced pharyngeal blennorrhæa in the course of about three weeks.

Dr. ANDREWS closed the discussion, and spoke of the variable effect of solutions of jequirity in different patients, and said we should always begin with a weak solution, say one per cent.

NEW YORK PATHOLOGICAL SOCIETY.

Meeting of May 14, 1884.

The President, Dr. GEORGE F. SHRADY, in the chair.

DOUBLE PLEURO-PNEUMONIA, PERICARDITIS, AND PERITONITIS.

—Dr. W. P. NORTHRUP presented specimens from a single case illustrating a set of lesions in two cases, double pleuro-pneumonia and pericarditis in one, and double pleuro-pneumonia, pericarditis, and peritonitis in the other. The children were taken sick the same day—at a time when there was a very abrupt change in the weather from a warm, relaxing atmosphere to a damp and raw day. He thought the cases of interest because neither child had had measles or scarlet fever, the apparent cause of the disease being a change in the weather.

Dr. LEVI thought that inflammation occurring in three of the serous membranes rather militated against the idea of the ætiology given by Dr. Northrup.

SUBMUCOUS FIBROID OF THE FUNDUS UTERI; REMOVAL BY THE SERRATED SPOON; PERFORATION OF THE UTERUS; DEATH.

—Dr. C. C. LEE presented a part of a fibroid tumor of the uterus, the woman having died under his care from an attempt to remove the growth by a method which had heretofore been considered free from danger. She was single, forty years of age, and had been sent to him to be operated upon in his service at the Woman's Hospital. About fifteen years ago she began to have excessive loss of blood at menstruation, and recurrent hæmorrhage at intervals. When she came under his care the tumor filled the upper two thirds of the uterus, which was dilated to the size of the seventh month of pregnancy. After several unsuccessful attempts at dilatation, the patient was anesthetized, and then dilatation was performed. It was very difficult to bring the uterus into a straight line above the pubes, it being strongly anteverted. The tumor was found to be sessile, and could be touched at about half an inch from the internal os. When it was brought into view it was found impracticable to embrace it with the wire of an *écraseur*, or to reach it with the scissors. An effort, therefore, was made at once to remove it by the process devised by Dr. Thomas—by the use of the serrated scoop. The operation consisted in slitting the cervix bilaterally, dividing the internal os sufficiently to gain free space for working, then grasping the presenting part of the fibroid with a strong vulsella, drawing it down, and endeavoring to insinuate the serrated scoop between the surface of the tumor and the inner surface of the uterus. This was extremely difficult, especially because of the anteverision of the womb. The house surgeon who assisted him by making counter-pressure constantly informed him that he could not feel the end of the scoop. Finding he could not detach the growth quickly in this manner, he determined to cut the tumor away piecemeal with scissors. In this instance the instrument, which in ordinary cases was perfectly safe, perforated the fundus and caused intra-peritoneal hæmorrhage. The woman did not fully react from the operation, and died within about twelve hours. At the autopsy it was found that the fundus, and also the posterior wall, of the uterus had been penetrated, and in the peritoneal cavity was fluid and clotted blood. He was not aware at the time when the womb was penetrated that he had gone beyond the base of the tumor.

Since this accident he had looked over the hospital records and found that two similar cases had occurred, one in the hands of Dr. Thomas and the other in the hands of Dr. Hunter, both patients dying. He related the case to show the dangers sometimes attending an operation which was usually considered perfectly safe. He did not believe there was any method yet devised by which such tumors could be removed without some danger to the life of the patient, and the woman ought to be informed of the risks before she was led to submit to an operation.

A POSSIBLE ÆTIOLOGICAL CONNECTION BETWEEN CEREBRAL HÆMORRHAGE AND A SMALL-SIZED AORTA.—Dr. F. FERGUSON presented specimens from the body of a man twenty-two years of age who had died in the New York Hospital. But a very meager history could be obtained. The patient was found one morning in the water-closet, at the place where he was employed, unconscious, paralyzed on the right side, with both hands clenched, and breathing heavily. When he was brought to the hospital the pupils were equal, but not responsive to light; there was paralysis of the entire right side, less marked in the upper extremity; he was unconscious; the respiration was slow and stertorous; the pulse 64. He continued in this condition until the following day, when the right pupil became much dilated, and the left side paralyzed. Just before his death the temperature went up to 108° F., death taking place three days after the stroke. At the autopsy all the organs were found healthy except the brain. A large effusion of blood was found

at the island of Reil, and all the convolutions were flattened. There had also been a large hæmorrhage within the brain on the left side, involving the ganglia. It was said the patient had been perfectly healthy up to the time of the accident. The case was of interest, because hæmorrhage in the brain occurred very seldom with a healthy condition of all the other organs, and without disease of the cerebral blood-vessels. The anomaly in the case related to the aorta, which was at least a third smaller than normal. This diminished size of the vessel might have been a mere coincidence, but Dr. Ferguson's attention was drawn to it from the fact that recently he had seen another case of cerebral hæmorrhage in which all the organs were healthy, the aorta, however, being a little less diminished in size than in the present case.

Dr. NORTHROP thought the aorta in the case presented by Dr. Ferguson was not much more than half as large as usual.

Dr. PORTER had seen a case of extensive cerebral hæmorrhage in a young man between twenty and twenty-five years of age in whom he could give no other explanation for the accident than long-continued malarial poisoning. There were also hæmorrhages into the spleen.

Dr. VAN SANTVOORT thought that, for want of a better explanation, we might suppose that in Dr. Ferguson's case the lack of development in the aorta was an indication of lack of proper development in the arteries generally throughout the body, making liability to hæmorrhage greater.

Dr. LEVI thought that defective elasticity of the artery attending its diminished size might make cerebral hæmorrhage more likely to occur.

Dr. PETERS related the history of a man who apparently brought on a fatal cerebral hæmorrhage by restraining his feelings while undergoing abuse.

Dr. CARPENTER inquired of Dr. Ferguson whether he had noticed a diminished size of the aorta in other cases than the two in which cerebral hæmorrhage had occurred.

Dr. FERGUSON said his attention had not been directed to the matter.

Dr. CARPENTER had noticed a small size of the aorta in at least two cases in which there was no hæmorrhage into the brain, but the diminution in size was not so great as in the case related by Dr. Ferguson.

CIRRHOTIC LIVER OF LARGE SIZE.—Dr. ELLIOT presented a specimen for which he was indebted to Dr. Boldt. The patient was a man, forty years of age, married, a butcher, who gave no history of syphilis, but not much addicted to drink, and had always been well except that during the past year he had suffered from chills and fever. In December last he noticed marked swelling in the right hypochondriac region, and respiration was somewhat interfered with. Ascitic fluid was drawn off. The man finally died of exhaustion. At the autopsy the special point of interest related to the liver, which was of large size, weighing ten pounds, the microscopic examination revealing a large amount of fat and an increase of the connective tissue.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

Meeting of March 26, 1884.

PAROXYSMAL FEVER, NOT MALARIAL.—Dr. J. H. MUSSER read the following paper:

That non-malarial intermittent fever is of frequent occurrence few will deny. Such cases have come to the writer's notice so often that, especially as but little can be found in reference to this subject in medical literature, arranged in a systematic manner, he has deemed it of the highest practical importance to record his observations, for the purpose of eupha-

sizing the value of distinguishing these two forms of intermittent fever. In addition to the hurried narration of illustrative cases, a little time will be taken for the consideration of the mode of recognition of the many sources of origin of paroxysmal fever, and a moment given to the mechanism of fever. It will not be out of place, however, to make a brief reference to the writings of others in this connection, and first to that of the late Dr. Murchison.

In a most instructive clinical lecture,* he called attention to all the forms of paroxysmal fever, giving twelve varieties, viz.: 1. Malarious intermittent fever. 2. Certain cases of typhoid fever. 3. Certain cases of relapsing fever. 4. Pyæmia. 5. Fever from pent-up pus. 6. Fever from ulcerative endocarditis, with or without embolism. 7. Tubercular fever. 8. Fever from lymphadenoma. 9. Syphilitic fever. 10. Urinary intermittent fever. 11. Hepatic intermittent fever. 12. Intermittent fever from morphine.

In addition to examples under each division, he pointed out the clinical features and points of distinction in such detail that it would be supererogatory to enter upon such lines, save in the broadest manner, in this paper.

In the following pages, therefore, cases illustrating the second, fifth, sixth, seventh, and eleventh classes, respectively, of the above, will be recorded, and some new classes will be added, embracing cases of paroxysmal fever due to gastro-duodenal and pulmonary catarrh, to pent-up serum, to forming pus in a confined space.

Since this paper has been in preparation, a volume of the latest "St. Thomas's Hospital Reports" (vol. xii, 1881) came into the writer's hands. Of the many able articles contained therein there is one by Dr. Ord, entitled, "On some Cases of Pyrexia simulating Ague." He records a case of ulcerative endocarditis, and one of jaundice with obstruction attended by intermittent fever. Similar cases are detailed below, and hence it will not be necessary to more than refer to them. Cases III and IV of his list are very interesting, and worth repeating in abstract.

CASE III.—Female, aged fifty-eight. Most of life in Mauritius. After returning to England, suffered from what was called ague—shiverings, heats, and sweatings at irregular intervals. At first no pain, but finally increasingly severe pain, attended with vomiting, was felt in the left iliac region. The symptoms repeatedly recurred for months and were regarded as outbreaks of latent ague acquired abroad. Treatment by quinine and arsenic. She finally, after a severe paroxysm, passed a stone the size of a bean from her bladder. Instant relief followed, and six months passed away (to time of writing) without any return of fever or sweating.

CASE IV is more remarkable, and, for the possibility of its like appearing to us, it should be kept in mind.

CASE IV.—A man, aged thirty, never in the tropics, had daily attacks of high temperature, with shivering and sweating. He was sallow, worn, and emaciated. His liver was enlarged; his spleen not. He had syphilis. The fever would be reduced by quinine, but only for a time. Thirty grains of iodide of potassium daily cured him, the intermittent fever having been considered by Jenner, in consultation, a manifestation of syphilis.

I. The temperature curve of typhoid fever simulates intermittent fever almost always at some period of its course. During the first week of the disease it is a difficult matter to decide whether a true intermittent is present or not, while in the decline of the disease a distinctly intermittent type is generally recognized. During the period of convalescence one must be watchful that the transient fever which so frequently develops

* "The Causes of Intermittent or Paroxysmal Pyrexia, and on the Differential Characters of its Several Varieties," "Lancet," May 3, 1879.

may not be considered malarial. The temperature during the course of typhoid fever, with the convalescence from it, is, as Dr. Cayley puts it, *labile*. It rises and falls with only the slightest provocation, and frequently takes on an intermitting type.

The following is a rare case of typhoid fever, in which the temperature at the height of the disease was distinctly intermitting. Dying the sixth day of observation, it was noted that four days before death the patient had daily a congestive chill, followed by a very high temperature. The temperature on the morning of the first chill was 101.2° (F.), the evening 104.4° . The morning temperatures thereafter were on the second, third, and fourth days, respectively, 98.6° , 99.4° , and 96.2° , and on the corresponding evening hour 104.6° , 105.4° , and 106.4° , the latter two hours prior to death. It was considered a case of congestive malarial fever. The autopsy revealed the lesions of typhoid fever about the twelfth day of the disease.

II. It is well known that the fever from pent-up pus is frequently, almost constantly, of an intermitting type. An empyema has frequently been overlooked on this account, but it has never fallen to the writer's lot to have a case that could not easily be recognized. It was different in other cases of deep abscesses, however, and notably in a case—the true nature of which, Murchison says, is almost always overlooked—of hepatic abscess.*

The patient, a male, thirty-nine years old, had lived on the Susquehanna, near Harrisburg, and had had chills and fever daily, three weeks prior to admission to the hospital. When admitted he did not seem very sick; he had walked to the hospital, and was permitted to be up each day. He was slightly emaciated and his liver was enlarged. He had daily paroxysms of fever, but the sweating stage continued all night, being more prolonged than in malarial intermittents. He died of hemorrhage from the bowels one week after admission. The hemorrhage was found to be due to extensive ulceration of the large intestine, not suspected during life, on account of the occurrence of constipation. In addition, at the autopsy a large abscess in the right and two small ones in the left lobe of the liver were found.

The following table exhibits the temperature record, and shows that we should have considered more seriously the low febrile range:

	A. M.	P. M.
October 9th.....	99°	100°
“ 10th.....	99°	101°
“ 11th.....	99°	102.6°
“ 12th.....	99°	101.4°
“ 13th.....	99°	102°
“ 14th.....	99.6°	101°
“ 15th.....	98.4°	99°

The history of residence in a malarious locality, the temperature record, the absence of marked local symptoms and of intestinal disorders, favored malarial intermitting fever; the absence of enlarged spleen and the low temperature range negatived that fever.

A child was seen with a history of daily febrile paroxysms, suspected to be malarial. The child had a severe paroxysmal cough, however, and was losing flesh and strength rapidly. An examination revealed the physical signs of circumscribed pulmonary consolidation, and the mother related the swallowing of a tack some time previous. Ten days afterward, after a paroxysm of coughing, the tack and a large amount of pus were expectorated. The hectic soon lessened, the resulting cavity rapidly closed, and the patient's health was restored. Another example of deep-seated abscess.

Abscesses developing near mucous surfaces are oftentimes very puzzling, at least in their early period.

An abscess of the prostate gland, in a man forty-eight years old, was one of the most difficult to discern. The patient had been sick a

week, and when seen by the writer was in the midst of a febrile paroxysm. He had marked gastro-intestinal derangement, with dry, brown tongue, extreme malaise, daily febrile paroxysms, preceded by chilliness, and followed by profuse sweats, which continued in the night; in addition, a dullness of intellect was observed. Six days after the first visit urinary tenesmus was noticed, subsequently rectal distress; an examination revealed a distinct prostatic abscess. It is of interest to note that fever did not occur after the abscess had fluctuated, and hence that the forming stage of an abscess sometimes is attended with paroxysmal fever. The following exhibits the evening rise and morning fall, taken on different days:

13th, 4 P. M.	102.6°
14th, 4 P. M.	99.2° , cinch. anticipated.
15th, 12 M.	102° , cinch. in lessened doses.
16th, 12 M.	98.5° , cinch. in increased doses.
17th, 11 A. M.	98° , cinch. in increased doses.
18th, 5 P. M.	103° , cinch. in again lessened doses.
19th, 9 A. M.	98.6° , 5 P. M., 103° .

A febrile paroxysm was not detected after the 20th, and the table shows that cinchona merely prevented the paroxysms, but did not control them. The case was certainly difficult to analyze. The absence of enlarged spleen, the return of the fever after discontinuing cinchona, and the exhaustive sweats, repulsed the idea of malaria. The appearance of the tongue, the malaise, the headache, and the dullness of mind, with the fever range, made one consider typhoid rather seriously. On the sixth day (19th) after my first visit the local symptoms defined the lesion. The febrile action then ceased, but the local inflammatory condition continued. It would probably explain the cessation of fever with complete suppuration to say that the soft tumor was not so much an irritant as the hard mass prior to pus formation.

Not only must pent-up or forming pus be considered factors in the causation of a periodical fever, but confined serum or forming serous exudation may undoubtedly give rise to intermitting fever. A case of subacute pleurisy with effusion, in which there occurred in the course of the disease distinct intermitting fever, came under the writer's notice. The usual evening exacerbations were present, but in the morning the temperature had fallen to, or almost to, normal. So marked were the paroxysms that an empyema was suspected, and doubt only removed by paracentesis proving the effusion to be serous. Two similar cases have come to his notice in private practice, both in children. The one, a lad eleven years old, had a dry cough for three weeks, with afternoon malaise and fever. The attendant ordered quinine with but little benefit. An examination of the lungs revealed a large collection of fluid in the left pleural sac, which rapidly disappeared under treatment. The temperature was recorded but once daily for obvious reasons, but at times in the mornings, again in the evening. Invariably an evening rise and morning fall, were noted; but it never ranged higher than 102° , and there were no profuse sweats following. From the rapid disappearance of the fluid and the speedy renewal of the lad's health, the effusion was called serous and not purulent.

It may seem very trite to record such simple cases, but when, only lately, a child was seen in consultation, ill from a supposed meningitis, but truly so from an actual serous pleuritic effusion, one should feel that nothing is commonplace, and that it is the little things that need to be constantly dwelt upon. With this remark it may be stated that the fever of pneumonia may be intermitting. Later in the paper cases of catarrhal pneumonia will be referred to, but now the croupous variety is considered. Four cases, all in children, are recorded in the writer's note-book. Two of the cases were in his care from the first; two were attended by other physicians, coming to him later.

* "Trans. of the Path. Soc.," vol. viii.

In the first case he was egregiously deceived. The child, aged four, for five days was well to all intents and purposes in the morning, eating and playing about, with possibly only a slight cough. In the afternoon the temperature would rise to a great height (104.4°), and the child would be sick until midnight. Repeated examinations of the lung could not detect a pneumonia until the fifth day. He was misled by the absence of dullness and of bronchial breathing, and the occurrence of tympany over the affected lung, as has been rarely noted.

Case number two, of the same character, occurred in a girl seven years old. A chill, followed by high fever, with nausea and vomiting, substernal pain and cough, marked the onset. Seen the third day, her temperature in the evening was 104.2°, with the above symptoms intensified, and a very rapid pulse (140) and rapid respiration (48). Both the fourth and fifth days the temperature was normal in the morning, high at night. On the fifth day bronchial breathing was first noted at the right base; on the seventh day, dullness; on the ninth day resolution began; after the fifth day the fever was continuous. It seemed like a case of retarded pneumonia—as regards physical signs—according to the observation of Dr. Andrew Clark.

Following the outline indicated by Murchison, the next form of intermittent fever he discusses is that due to endocarditis. The following case* of ulcerative endocarditis, the febrile range of which was characterized by daily paroxysms, is of interest. There was no difficulty in recognizing the nature of the affection.

TEMPERATURE RECORD.

	A. M.	P. M.
21st.....	1—	103.4°
23d.....	100.2°	101.6°
23d.....	98.4°	99°
24th.....	98°	105.4°
25th.....	97.2°	103.2°
26th.....	99°	103°
27th.....	99°	100.4°

The writer observed it during life, and deems it worthy of being recorded in this connection.

It would be a great surprise to know how many persons, in the latter stages of phthisis, when giving a history of their complaint, say that it was preceded by malaria, or malaria broke them down. Over and over again is such a sad tale told us in the medical dispensary, and it is a matter of fact that not only do the laity but many physicians consider early cases of phthisis as malarial in nature, entirely overlooking the local troubles. When speaking of catarrhal fever, the subject will be adverted to again, but the cases of tubercular origin are sometimes none the less examples of intermittent fever, non-malarial. Repeatedly my notes show cases that had been treated for malaria in the early stages. Not only in the formation of tubercle in the lungs, but also in the brain, is the process accompanied by daily paroxysms of fever at times. One case that came under notice was particularly impressive.

The attending physician was going out of town for the summer, and left in the writer's care a little girl, five years old, in the fourth week of her fatal illness. She had always been a bright child, of nervous temperament and of tubercular diathesis. The illness was of four weeks' duration, marked in the early period by failing in flesh and strength; in the latter period by a chill or chilliness every evening, followed by a night of restlessness and fever. She never complained of headache, nor did she vomit, while her bowels were regular. Eight days before the present attendant saw her, her physician visited her, and attributed the symptoms to malaria; quinine was used. Four days thereafter headache began. The day the writer saw her (fourth week) she had had a slight convulsion and other unmistakable evidences of tubercular meningitis, of which she died in seventy-two hours.

How terrible to be compelled to tell a fond mother the inno-

cent malaria only simulated the baneful meningitis! The writer once made the mistake of attributing a periodical headache to malaria; tubercular meningitis was the cause of the pain. It is seen then, and is well known, that many manifestations of that disease are periodical.

The succeeding case of chronic hepatitis with enlargement illustrates that form of intermittent fever which is hepatic in origin. The diagnosis was made without difficulty, especially the differentiating from intermittent fever of malarial origin. The following abstract of the history includes all the important points:

George W.,* aged forty-three, German farmer, of Manayunk, contracted diarrhea during the war, which has always shown some tendency to return. Has had malaria; probably has had syphilis; otherwise been very healthy. Family history good. Admitted September 2, 1877, with well-marked jaundice; emaciated, and presented the symptoms of itching, dark colored urine, languor and sleepiness, and a small, slow, and feeble pulse.

The jaundice appeared gradually in February of 1877, preceded by several days of diarrhea. Since then marked dyspeptic symptoms, relieved by attacks of diarrhea; stools at times clay-colored, at times normal. Some edema of feet, but ascites never detected. October 2d, liver from fourth interspace to two inches below margin on deep percussion, margin smooth and resisting; no pain or tenderness. October 15th to 25th, uncontrollable hicough. Extreme exhaustion, rapid emaciation, deepening jaundice, semi-typhoid state; death, November 4th. Autopsy revealed the diagnosis to be correct.

The temperature record is noted with the remarks of Dr. Guiteras, whose resident physician the writer was at the time, on its curious range, in order to associate the case with a paper on fevers.

"I find that every third temperature is pretty regularly a high one, the fall being very great in the two intervening temperatures; so that the rise and fall do not present the usual relations to the morning and evening hours. The curious range of temperature may be due to an intermittent absorption of effete products from the liver, or an intermittent arrest of the oxygenating processes going on in the liver, an arrest that must influence the general temperature, if we remember that in health the temperature of the organ reaches 106°."

In another paper† of the writer may be found reported a case of primary cancer of the gall-bladder:

Early, in fact almost until death, the attending fever was thought to be of malarial origin. The writer, as well as others, made the mistake. Until a few months before her death the fever was distinctly intermittent with chills; later it became remitting and then continuous. Although there were jaundice and occasional attacks of vomiting, there were no special evidences of localized disease. The spleen was enlarged, and so it was thought to be a miasmatic fever. The change in type, the extreme exhaustion, and the emaciation caused this idea to be abandoned. Until death it was obscure. A sufficient cause for the temperature range was found at the autopsy in a suppurative inflam-

* "Trans. of the College of Physicians," Keating.

* "Trans. of the Path. Soc.," 1878.

† *Ibid.*, 1881.

mation of the bile ducts, and the healthy portion of a gall-bladder, the remainder of which was the seat of carcinoma. One can see now that more stress should have been laid on the occasional vomiting, the slight hepatic tenderness, the previous history of biliary colic, the persistent and deepening jaundice, and the great emaciation, and thereby a diagnosis been made between miasmatic fever and suppurative fever.

Here will briefly be recorded two cases illustrative of the fever of hepatic origin, not because of one difficulty in their recognition, but because one of them, the first, had been treated for malaria.

This one was the case of M. Mc., aged fifty, who suffered at irregular intervals, often repeatedly in a week, with attacks of severe pain in the epigastrium accompanied by a chill and followed immediately by fever and sweat, and in a few days by jaundice. He died several months afterward, in the writer's care, of obstructive jaundice from impacted calculus, after two of these attacks in succession.

When these attacks occurred, every day or every second day, it can be readily seen how a mistake in diagnosis could have been made. Attention to details, however, with the therapeutic test would have been good aid. The paroxysms, by the way, were no doubt due to the irritation of the discharging calculus. The other case was that of an impacted, possibly ulcerating biliary calculus. The history of the case, the jaundice and the local inflammatory changes prevented one from erring.

In addition to the preceding examples of paroxysmal fever, a series of cases will be adverted to which Murchison has not referred to in his lectures, and with the nature of which it is of the utmost importance to be perfectly familiar. Reference is made to catarrhal inflammations of pulmonary, the gastro-intestinal, and the genito-urinary mucous membranes, with secondary intermitting fever resulting therefrom. Especially important is it, for, unless the fever is traced to its source, grave organic mischief will become so pronounced as to lead to disastrous consequences. Witness a phthisis following an overlooked bronchial catarrh.

It savors much of the teachings of Broussais to say that catarrhs are the source of fevers, but there is no doubt that just so far as the philosophic Frenchman erred in that extreme, so do we at the present day err in the other, by attributing most fevers to a zymotic process. Professor Pepper,* in a timely and instructive address, calls attention to these dangers: That fever is too often considered as due to a zymosis; that zymotic diseases are of self-limited duration; hence that active treatment is of no avail, and especially that the accompanying catarrhs are neglected. Further, on account of these beliefs, the catarrhal process that is often the cause of a fever is overlooked, and thus the commencement of serious local disease is not thwarted.

Reference was made, in another portion of the paper, to the frequency of assuming early tubercular disease of the lung, accompanied by intermitting fever, to be due to a miasmatic fever. The following notes illustrate the clinical course of some cases of catarrhal disease of the air-passages, which often are the forerunner of so-called catarrhal phthisis. Other examples have been noted, in which there has been only slight catarrhs, without hemorrhage, much cough or emaciation, with attendant fever, occurring in paroxysms.

One of the most typical cases of paroxysmal catarrhal fever came under observation in August, 1880, and was the first to lead to the investigation of this question.

A man, forty years old, of previous good health and habits, of good family history, and residing in a healthy neighborhood, sought advice

for "chills." Daily at 11 A.M. he would have a chill, followed by fever and sweat. The entire paroxysm continued until 6 P.M. His digestion was impaired, and his bowels were constipated. The usual treatment was employed. He reported twice that the chills had ceased to return at once when the medicine was finished. He also reported that his sweats continued throughout the night, and that he was losing flesh and strength. At the third visit he was much dissatisfied, for a former slight cough had grown more pronounced, he had bloody mucous expectoration, and the chills continued. Upon careful examination, a distinct area of consolidation at the root of the right lung, with attending blowing breathing, and some subcrepitant râles were found. Active treatment was determined upon, and in six weeks the patient was cured. He has followed his occupation ever since (engineer), is heavier than he ever was, and in perfect health.

Further: A young miss of twenty years, the past winter, was conducted through an attack similar in many respects. Originating in a severe cold, with harassing cough, chest pain, no expectoration, and with loss of appetite, nausea, and constipation; she lost flesh, and had, the first two weeks of her illness, daily morning chilliness, fever in the afternoon (102°), followed by an exhaustive sweat. During this time the physical signs of a bronchitis were present, with marked localization of the inflammatory process at the right apex. A day of undue exposure and exertion was followed by a severe chill and rapid rise in temperature, with distinct evidence of catarrhal pneumonia at the location indicated above. Chills and fever daily, profuse sweats, emaciation, and gastric derangement were prominent for two weeks. The former symptoms then subsided, but it was fully two months before the lung cleared up, and the patient gained flesh and strength. The family and friends constantly reiterated their opinion that the attack was primarily malaria.

Probably the most difficult, the most occult form of paroxysmal fever of catarrhal origin to recognize is the one due to that lesion of the intestinal tract. There are no physical signs to betray it, and generally the intestinal derangement is considered secondary to the febrile process. It seems impossible to distinguish the specific from the catarrhal form, save by the presence or absence of the enlarged spleen, the change in the urine of malarial subjects and of the blood when the malaria is chronic, especially when a recent writer tells us that epigastric pain, vomiting, and constipation are symptomatic of malaria in children. The following record is a typical illustration of this variety, and is a most instructive and pertinent case:

E. M., aged five. Inherits a tubercular diathesis from mother. During November and December of 1881 had no appetite, was obstinately constipated, and lost flesh. She became delicate and puny-looking. The latter part of December she was seen on account of the above symptoms and of an irregular fever. The course of the fever was at first difficult to determine, but finally it was found to be distinctly intermittent. She was visited at various hours of the day, and found that at 11 A.M., daily, she would be cold, shivering, and begging for extra covering. Her extremities, nose, and ears would be very cold, her lips bluish, and the features pinched. At the same time the pulse would be rapid, and the temperature in the mouth 102°. In a half-hour the exterior warmed, and very soon she would have high fever, the temperature rising to 103°-103.2°. The febrile stage lasted three or four hours, and was not followed by profuse perspiration. Save weak and without appetite, by night she would be perfectly well. Quinia was given in continuous doses at first, afterward in doses to anticipate the paroxysm; but without any good effect. The paroxysms were lessened in severity only while the already poor appetite was made poorer and the digestion more impaired; for two weeks an anti-periodic treatment was continued, and at the same time laxatives were used to overcome the constipation; at this time (January, 1882) she was thin and worn, the paroxysms of fever were daily, the appetite was very poor, the breath offensive, the tongue covered on the dorsum with a yellow-white fur, pointed, and with no papillae; vomiting occasionally occurred, and always some pain after eating; the bowels remained obstinately constipated. It seemed to me, after a time, the fever was a

* "On Some of the Relations of Catarrhal Affections," "Trans. of the Am. Med. Assoc.," 1881.

secondary matter, that the gastro-intestinal disorder was primary, and that such disorder was subordinate to the diathetic constitution. Hence she was placed on small doses (one eighth grain) of calomel with bicarbonate of sodium (five grains) every three hours. In three days cod-liver oil with syrup of the hypophosphate of lime was added to the treatment. At once she began to improve; her appetite first, then her bowels became more regular. In two weeks the child rapidly improved under this treatment, after being treated previously for more than two weeks for malaria. It may be added here that twice or three times E. became constipated with similar febrile symptoms noted above, and that the parents, without my advice, cured her with the cod-liver oil mixture.

A case very similar to this was also seen. It is useless to report the details of the case; remedies directed to the gastro-intestinal catarrh, with accompanying intermitting fever, effected the cure.

A case of stricture of the pylorus, in its course, at one time presented daily chills and fever. Quinine did not control the paroxysms. During the time of the fever, and for a week afterward, the stools of the patient were composed of mucous or membranous casts of the intestinal canal or of a pulaceous mucoid discharge.

These cases incontestably prove the proposition that intermitting fever is often due to catarrhal inflammation of the intestines, and that remedies directed to this locality alone will cure the disease.

This clinical record will be closed by the report of an observation of a case, the nature of which is somewhat obscure. It is not given, therefore, without some misgiving. It appears that the only title that could be applied to it would be paroxysmal fever of neurotic or hysteroid origin.

The patient was twenty-five years old, of a rheumatic diathesis and nervous temperament. She presented a history of "chills and fever," recurring at irregular intervals for two years. The paroxysms were of the quotidian type and the attacks lasted one or two weeks. Considered to be malarious; quinine or cinchona was always given by her attendant, and the usual remedies for malarial toxæmia used, without cutting short or preventing the attacks. The writer attended her through two attacks. They were of the following nature: Preceded by dyspeptic symptoms for a few days, a violent chill attended the onset of the attack, accompanied by severe headache, with tender spots and one or more localized points of pain in the body. In one of the attacks the pain with the first chill was fixed at the end of the spine with exquisite tenderness; in another it was in the epigastrium. The chill was an hour in length and followed by fever. With the fever the face would flush, the eyes "burn," and the skin be hot and dry. The temperature would rise to 103° or more, the pulse be full, bounding, rapid. Evidences of gastric catarrh with constipation were also noted. During the paroxysm the most pronounced emotional disturbances were manifest, so that had fever been absent it would have been without difficulty considered a case of hysteria. A sweating stage of two hours followed the fever.

The paroxysms recurred daily for a week, but with the repetition of each one the pain would be seated in another portion of the body—in the occiput, the shoulder, or the knee-joints—while the emotional disturbances would be also present. The pain was described as unbearable, and could not be influenced by almost incredible doses of the usual anodynes. Quinine was given in enormous doses in the first attack, without any beneficial influence.

The fact that the paroxysms occurred toward night and that they were accompanied by hysterical symptoms of a high degree, the inutilty of quinia and the absence of enlarged spleen rendered the opinion that the case was of neurotic origin probable.

The second attack was very similar. Vomiting was, however, a more persistent symptom. The duration was about one week, and it appeared to yield to remedies addressed to the hysteria and the gastric irritability. The whole tenor of the patient's life has changed since then, so that for two years she has not had a return of the supposed malaria, notwithstanding she is exposed to the same malarious influences.

Time will not permit a review of the various affections in detail, in order to establish a differential diagnosis between these simulative disorders and a true intermittent. Any attempt at a positive diagnosis of paroxysmal fever, however, should not be made without keeping in mind the following proposition: In the first place, one would say that, given a case with a chill and fever, a diagnosis of intermittent ought not to be made from the nature of the first paroxysm, unless it be vital to do so, as in a pernicious intermittent. Then, if such a case is presented that yields but partially to anti-periodics, they should be discontinued and a fresh start in the diagnostic inquiry taken.

In order to fully establish a diagnosis, a careful study of the antecedents of the patient should be made relative to previous health, habits, place of residence, and family history. Then, in favor of malarious intermittent, we should, after this study, expect a morning hour for the chill (Flint), the well-known changes in the composition of the urine, and, if chronic, the enlarged spleen and the pigment granules in the blood. If with one or more of these favorable factors present we could exclude all possible source of organic disease, by an examination of each individual organ, the blood (leukæmia), the eye ground (tuberculosis), the lungs, liver, and gastro-intestinal tract, we would be warranted in the diagnosis of malarial intermittent.

It seems, further, to be of value to note that emaciation of a high degree is more common in non-malarious intermittents.

The same may be said of exhaustion. The latter occurs to a certain degree, and is attended with a pronounced anæmia, so easily recognized as of malarial origin. Then, too, a long sweating stage and a low febrile range rather disprove the presence of the malarious influence.

Enlargement of the spleen is not to be considered, in acute intermittents, as of little moment. In a series of twelve cases of intermittent in children, eight presented the enlargement, which had subsided a year after the first examination.

There is but little doubt that fever is of neurotic origin, and the examples which have been recorded to-night more aptly illustrate this cause than any other class of cases. The profession is so thoroughly imbued, however, with the idea of no fever, unless a zymosis or blood-poisoning, that it is of practical value to refer to the mechanism of fever briefly. As shown by others, disastrous results oftentimes ensue by addressing means to the cure of a zymosis, or by passively allowing a febrile process to continue its supposed self-limited course, when actually a zymosis was not present, and remedies otherwise applied would have been beneficial. The reference to the mechanism, therefore, is to show that often fever is of a reflex origin due to peripheral irritation—a neurosis.

The element of intermittency itself is a powerful argument in favor of its neural origin. This is not the time to engage in philosophical speculation, or to demonstrate the relation of the fundamental principle of the rhythm of motion so grandly elaborated by Spencer; suffice it to say that to no other set of tissues or systems could we look but the nervous system for an explanation of intermittency. Aside from this, however, in the masterly study in morbid and normal physiology by Wood, on the mechanism of fever, we find sufficient argument and proof "that a depressing poison or a depressing peripheral irritation, acting upon the nervous system which regulates the production and dissipation of animal heat," causes fever.

Among the illustrations presented to-night there are some which strongly indicate the reflex origin of fever from peripheral irritation; witness the case of vesical calculus or of gall-stone. By what other supposition could the phenomena be explained? Likewise, though with an element of doubt intermingled, in the cases of gastro-intestinal catarrh, the fever may be considered as due to reflex processes. In the other cases the

fever is, no doubt, due to the absorption of a poison which acts upon the nervous system, and, as opposed to Charcot and Billroth, one would think that the phenomena of intermittency are due not to paroxysmal discharges of pus or poison into the blood, but to rhythmical responses of the nervous system to a constantly acting poisoned blood.

Miscellany.

THERAPEUTICAL NOTES.—*The Symptomatic Treatment of Typhoid Fever.*—The "Progrès médical" cites the following from a work on clinical medicine recently published by M. Gueneau de Mussy:

For allaying *pains in the limbs and cutaneous hyperesthesia*, the author recommends the employment of the following liniment:

"Baume tranquille".....	100 parts;
Rousseau's laudanum,	
tincture of belladonna.....	aa 15 "
chloroform.....	10 "

["Baume tranquille" is an infusion of a great number of narcotic and aromatic plants in olive oil. One hundred and twenty-eight grammes, each, of the fresh leaves of belladonna, of hyoscyamus, of dulcamara, of tobacco, of the poppy, and of stramonium are boiled over a slow fire in 3 kilogrammes of olive oil. After standing for two hours, the mixture is strained with expression, and, while yet warm, is poured over 32 grammes, each, of the dried tops of absinthium, of lavender, of hyssop, of marjoram, of water-calamin, of balm, of St. John's wort, of rue, of sage, and of thyme, and of the dried flowers of elder and rosemary. It is then allowed to macerate for a month in the sun, in a closed vessel, after which it is strained, decanted, and kept away from the air and light.

Rousseau's laudanum is an aqueous solution of opium, which is fermented with yeast, and then distilled several times.]

For *persistent insomnia* M. Gueneau de Mussy gives a teaspoonful of the following mixture at bedtime, to be repeated every two hours until sleep results:

Linden water.....	50 grammes;
orange-flower water.....	40 "
mint water.....	10 "
cherry-laurel water.....	5 "
syrup of codeine or of morphine.....	25 "
bromide of sodium or of potassium.....	4 "

To *prevent bed-sores*, he paints the parts once or twice a day with collodion and castor-oil, with equal parts of alcohol and white of egg beaten together, or with "traumaticine" (a solution of gutta-percha in chloroform—4 parts to 30). If an excoriation forms, the following ointment is applied:

Cerate or cold cream.....	30 grammes;
extract of cinchona.....	1 to 3 "
precipitated oxide of zinc.....	1 gramme;
watery extract of opium.....	15 centigrammes.

For *phlebitis*, the following application is made along the course of the affected vein:

Purified lard.....	30 grammes;
watery extract of opium.....	
extract of belladonna.....	} aa, 3 "
extract of hyoscyamus.....	
extract of conium seeds.....	

In addition, poultices are applied.

The Active Principles of Ergot.—At a recent meeting of the Berlin *Gesellschaft für Geburtshilfe und Gynäkologie* Dr. M. Marckwald gave the results of a number of experiments made by him, in the physio-

logical institute of that city, with ergotin, ergotinin, and sclerotinic acid. Practically, he had found ergotinin inert. Both ergotin and sclerotinic acid acted efficiently, and he would consider the latter and its salts preferable, on account of the small size of the dose required, were it not for their irritant action. Dialyzed ergotin, prepared from good material, he regarded as thoroughly trustworthy, and not liable to produce inflammation when used subcutaneously.

Burnt Alum in the Treatment of Intermittent Fever.—Dr. A. Sawinsky recently reported to a Russian medical society ("Deutsche Medizinal-Zeitung") that he had tried the use of burnt alum in twelve cases of intermittent fever, and successfully in each instance. He gave the remedy in doses of eight grains twice a day, and he found that it was well borne even in doses of twenty-four grains, provided a glass of water was drank after the dose.

THE "DICTIONNAIRE DE MÉDECINE."—Professor Ch. Robin writes to the Paris medical journals asking them to give publicity to the fact that the new edition of the dictionary edited by the late M. Littré and himself has not been revised by him, in consequence of which he thinks that the publishers were not warranted in inserting his name on the title-page.

THE MASSACHUSETTS MEDICAL SOCIETY.—The one hundred and third annual meeting will be held in Boston on Tuesday and Wednesday, June 10th and 11th. On Tuesday, at noon, the following communications will be presented at the building of the Harvard Medical School: Methods of Instruction and Research in Physiology, with Demonstrations, by Dr. H. P. Bowditch, of Boston; Modern Methods in Anatomy, with Demonstrations, by Dr. Thomas Dwight, of Boston. At the afternoon session, in Huntington Hall, Dr. G. W. Gay, of Boston, will read a paper entitled *The Plaster Posterior Splint in the Treatment of Fractures of the Leg, with its Practical Application*. At the Wednesday morning session the following papers will be read: A case of Chylous Deposit in the Abdomen, by Dr. F. Nickerson, of Lowell; The Pitch of the Percussion Sound, by Dr. L. Huntress, of Lowell; Sanitary Forest-Culture, by Dr. J. F. A. Adams, of Pittsfield; Weight as an Indication of the Character of Risks for Life Insurance, by Dr. J. Seaverns, of Roxbury; Communications from the Reporters of the District Societies. The annual discourse will be delivered at noon, by Dr. John Crowell, of Haverhill.

NIAGARA UNIVERSITY.—The following is an extract from the bill lately passed empowering the university to grant medical degrees, to which we recently made brief allusion: . . . "and the said college shall have the right to maintain a medical department and any department of learning that is maintained by any college or university in this State, and may maintain any department thereof, and enjoy and exercise all or any of the powers, rights, and franchises thereof in the county of Erie; and the trustees of the said college shall have the power and right to grant and confer any degree which may be or is granted and conferred by any college, university, or other institution of learning in this State legally authorized so to do; and every diploma given in testimony thereof shall entitle the possessor to all the immunities and privileges which by law or usage are allowed to possessors of similar diplomas granted by any college, university, or other institution of learning in this State. And the trustees of said college may grant and confer the degree of doctor of medicine; but only upon the recommendation of the board of medical professors of said college, and of at least three curators of the medical profession fully and legally qualified to practice medicine and surgery, to be appointed by said trustees, and which curators shall not in any manner be connected with said college; but no person shall receive a diploma conferring such degree unless he be of good moral character and of the age of twenty-one years, and unless he shall have a good English education, and shall have pursued the study of medicine and the sciences connected herewith at least three years after the age of sixteen years, and received instruction from a physician and surgeon legally authorized to practice his profession, until he is qualified to enter a medical college, and shall also after that age have attended at least three complete courses of lectures in the medical department of some legally incorporated university or medical school, the last of which courses shall have been so attended in the medical department of said college."

Original Communications.

OVARIOTOMY.

By JAMES B. HUNTER, M.D.,

SURGEON TO THE WOMAN'S HOSPITAL; PROFESSOR OF GYNECOLOGY IN THE
NEW YORK POLYCLINIC, ETC.

Preparation of the Patient.—An operation having been decided upon, a few days should be devoted to the preparation of the patient. If she has traveled some distance, time should be allowed for rest. All family affairs should be disposed of early, and nothing that can cause anxiety should be left till the last day. Special care must be taken to have the bowels thoroughly but gently opened, and for this purpose mild aperients are to be given every night for several nights. This is much better than trusting to a powerful cathartic given once or twice. It is quite possible for the patient to have a movement of the bowels every day, and yet to have a quantity of hardened fecal matter impacted in the lower bowel, the expulsion of which subsequent to an operation sometimes causes great pain and disturbance, and even a high temperature. This matter should therefore always be given particular attention; both patient and nurse may be mistaken in supposing the bowels to be thoroughly open when they are not so. The urine should be examined more than once. The presence of albumin in any considerable quantity greatly increases the danger of prolonged anesthesia. If time permits, a hot bath, followed by anointment with oil or vaseline, should be given by a skillful nurse every night for a week before the operation, to insure the fullest activity of the skin. Nourishing and easily digested food is to be given at regular intervals. Stimulants are very rarely necessary, and the patient is generally better without them. If she suffers pain it should be relieved by opiates, and if she is wakeful the bromides should be given at bed-time. Out-door exercise should be taken if possible, and the mind pleasantly occupied, and diverted as much as possible from the operation and its details. A large enema of hot water should be given twelve hours before the operation. Absolutely no food is to be allowed for five hours before the administration of the anæsthetic. It is better not to let the patient pass the urine immediately before the operation. Its presence in the bladder renders that organ more conspicuous, and it is therefore less likely to be injured.

The Operating-Room.—The room in which the operation is to be performed should be the object of special care for some time beforehand. It should have no stationary wash-stands, and there should be no water-closet adjoining. The furniture it contains should be limited to what is absolutely necessary, and should be as plain as possible. Carpets, woollen curtains, and upholstered furniture are all objectionable, and had better be dispensed with. If the walls are not papered, they as well as the ceiling and floor are to be thoroughly washed with hot carbolized water. Papered walls can not be washed in the same way, but they can be cleansed by passing over them a cloth damped in some anti-

septic solution. Two days before the operation the room should be closed and fumigated by the combustion of sulphur, or the elimination of chlorine gas. After this the room is to be thoroughly ventilated. For an hour before the operation the room is to be sprayed with carbolized water. The moisture tends to precipitate the floating particles and purify the atmosphere. The temperature of the room should be raised to 75° F., and maintained there during the operation. It is safer to have it above that point than below it.

All the precautions recommended in the preparation of the apartment may not be practicable in every case, but, if their importance is insisted on, they will not be found to present much difficulty, as they certainly do not involve much expense.

Instruments.—The following instruments, if carefully selected, will be found sufficient for all ordinary cases of ovariectomy: One scalpel; two small tenacula; one narrow and one broad director; one pair of scissors; six pairs of pressure-forceps; one trocar, medium size, curved or straight; one male sound, No. 6; two large tenacula; two Nélaton's forceps; two retractors; two needle-holders; needles; twelve sponge-holders; glass drainage-tubes; clamps; Paquelin's thermo-cautery.

In addition to the foregoing, it will be necessary to provide silk and catgut ligatures of various sizes, including several long and very strong silk ligatures for the pedicle. Silver wire, No. 26, is needed for closing the abdominal wound. One dozen hand-sponges should be provided, and the same number of small sponges for the holders. Also rubber adhesive plaster, and antiseptic dressings. As the operation of ovariectomy is one full of surprises, it is well to be provided with a clamp of extra size, as devised by Dr. Thomas for cases where it is necessary to remove a portion of the uterus, and also with Thomas's hard-rubber double drainage-tube, which is invaluable in certain cases where the cyst can not be wholly removed.

The only other appliances necessary are a tub or other large vessel to place under the table, two or three small basins, a large piece of rubber cloth, a roll of fine cotton wool, and a broad bandage to complete the dressing. A rubber or lead coil, for refrigeration, should be in readiness for use at any time after the operation.

During the operation the instruments are to be kept in a tray or shallow dish and covered with a five-per-cent. warm solution of carbolic acid. The bichloride solution should never be used for instruments. It not only injures them by destroying their polish and dulling their cutting edges, but the solution itself is decomposed and rendered inert by contact with metal, the mercury being deposited upon it in metallic form.

The silk ligatures may be kept during the operation in a solution of bichloride, one to two thousand, or in a five-per-cent. solution of carbolic acid. It is best to keep both silk and catgut in jars or wide-mouthed bottles, with small apertures through which the ligatures are withdrawn as needed for use. When not in use, the antiseptic solutions in which the ligatures are kept should be poured off and replaced by

alcohol, as the solution of bichloride weakens the silk and renders the heaviest ligatures unreliable.

The solutions of bichloride and of carbolic I formerly had made with distilled water, but I now use exclusively water taken from a boiler supplying steam for an engine. If it is a low-pressure engine, the temperature of the water will have been raised about fifty degrees above the boiling point. In a high-pressure engine the temperature of the water in the boiler is much higher. The purity or impurity of the water used at operations is, in my opinion, a frequent source of danger, and may easily invalidate all the other antiseptic precautions. Some forms of bacteria are known to survive a temperature of 212° , but are entirely destroyed by a higher temperature. It is therefore desirable to obtain water for antiseptic solutions that has been subjected to the purifying influence of a very high temperature; and water from the boiler of an engine, which can be easily obtained almost anywhere, is probably the purest that is available. Neither the water nor the solutions made with it should be exposed to the air unnecessarily, but should be transported and kept in demijohns or other glass vessels until required for use.

Anæsthetics.—Ether is the best and safest anæsthetic, but it should be administered in such a manner and with such care as to obtain the desired result with the smallest quantity possible, and with the least discomfort to the patient. This is most readily accomplished by the use of Allis's inhaler, which, if properly managed, supplies the necessary amount of air in combination with the vapor of ether, and is very much better than any form of cone, or any other inhaler I have tried. The patient should be prepared for the effects of the ether by assuring her that after a few moments, if she breathes boldly, she will experience no unpleasant sensations. She should lie upon a bed or couch, with the head raised by a single pillow; the room should be kept perfectly quiet; she should then be asked to breathe deeply and rapidly a few times through the inhaler before ether is put into it. The inhaler is then to be saturated with the anæsthetic and placed over the mouth and nose, and the patient urged to breathe rapidly. If she pushes it aside it should be quickly replaced at the moment before an inhalation. The inhaler is then to be kept constantly wet with ether, care being taken not to allow it to run through on the patient's face or neck, and not to close the opposite end of the inhaler. From five to ten minutes will generally suffice to render the patient entirely unconscious, and she can then be placed on the operating-table. A small quantity of ether uniformly administered will then keep her under its influence. I now invariably use Squibb's ether, having had no satisfactory experience with any other. The art of giving ether in the best way is a valuable accomplishment. It makes a vast difference to the operator if this duty is so performed as to relieve him of all anxiety. If, on the contrary, the patient is at one moment recovering from the effects of the ether, and at the next snoring and livid, the operator's attention is necessarily distracted, and it is impossible for him to devote himself entirely to the work before him. Therefore the assistant who administers the ether should attend to nothing else, and should take no interest whatever in the operation.

The Operator and Assistants.—The possibility that the operator may himself convey to the patient the germs of disease should never be lost sight of. He should not on the day of the operation have attended any case of a septic nature, as peritonitis, fever, or erysipelas, or of any contagious disease, or have dressed wounds of any kind. All other precautions will be in vain if the most scrupulous attention is not paid to personal cleanliness on the part of the operator and his assistants. Immediately before the operation the hands should be thoroughly washed in hot water, with soap and a stiff nail-brush; and afterward washed in the bichloride solution, the nail-brush being used in that also. The same ceremony is to be performed by all the assistants. No spectators should be present who have been making post-mortems, dissecting, or attending any contagious diseases, as the air of the room might be thus infected. Especial care is also to be observed regarding the nurses in attendance. The antiseptic precautions recommended should be carried out in the minutest details, and, if possible, under the personal supervision of the operator himself. An error on the safe side involves at most some trifling inconvenience; an error on the other side may cost the patient her life.

The Operation.—The patient, having been anæsthetized on a bed or lounge, is placed on the operating-table, the legs flexed and the feet resting on a chair or other support. A blanket is first placed under the legs and pinned around them. Another small blanket is fastened round the upper part of the body; the hands and arms are protected by towels or loose sleeves and secured in a convenient position by pinning, so as to be out of the way. The operator stands on the patient's right, the first assistant directly opposite. The second assistant stands to the left of the first, and takes charge of the instruments. The third assistant stands on the left of the operator and attends to the sponges, being assisted by a nurse who is stationed close behind him. The fourth assistant attends to the ether, and to nothing else whatever. A fifth man is desirable, to be ready for any work he may be called upon to do. It is a great advantage to have assistants who are trained to the particular work required of them in this operation, and to the ways of the operator; and with such assistants a smaller number will suffice. They are as regulars compared with volunteers. In any case each assistant should be instructed definitely as to what he is expected to do, and the operator should be an autocrat for the time being. No advice or opinion should be given unless asked for by any of the assistants, and silence should be preserved as far as practicable by all who may be present. At least two nurses should be in attendance—one to help with the sponges, and one to remain in close attendance on the operator.

Begin by making an incision, from a point about two inches below the umbilicus, two and a half inches long, cutting down to the muscles; arrest the bleeding, if necessary, by forceps, and leave them attached while the muscles are divided, as nearly as possible in the median line. If the abdominal walls are tense and thin, it is safer to divide the muscles and fascia on a director. A stratum of fat is usually met below the muscles, and should be cut through very carefully on the director, with scissors or knife. The peri-

tonæum will then appear, and must be divided with great care, lest the cyst be opened at the same time. The safest method is to pick up with a small tenaculum or forceps a portion of what appears to be peritonæum, and cut it with the knife or scissors held horizontally. As soon as the abdominal cavity is reached, a large male sound, dipped in a warm carbolic solution, is passed in and swept round the tumor to determine the extent of the adhesions, if any. The patient is then turned over on the side next the operator, and the exposed portion of the tumor fixed with a large tenaculum. A small trocar is then plunged into the tumor, a sponge being pressed under it to avoid contact of the fluid with any portion of the peritonæum. If the fluid flows freely, and the adhesions are not extensive, the punctured portion of the sac can be drawn outside the wound and seized with Nélaton's forceps. The trocar may then be withdrawn, and the tumor opened freely with the scissors to allow a more speedy emptying of its contents. If the tumor is a simple cyst, it may be drawn out without further manipulation, and the pedicle secured at once. While the tumor is being evacuated, and during the whole operation, the edges of the abdominal wound are to be protected by soft towels or napkins, wrung out of a hot bichloride solution, a number of which should be ready for use as called for. The abdomen also is to be kept warm by the same means. The assistant opposite is directed to maintain gentle but firm pressure on the walls, at the same time that he guards against the protrusion of the intestines. If it is a multiple cyst, the trocar may be used again more deeply, but in such cases it is a saving of time to pass the hand into the cyst and break up and evacuate the contents as rapidly as possible. If there are no adhesions, the collapsed sac is drawn out and the pedicle secured by transfixing it with a needle, which draws through the center of the pedicle a double silk ligature. The ligatures are tied separately, being first crossed so that when tied the loops interlock. This double knot, each portion of which is independent, is more secure than any device by which the two portions of the pedicle are tied at once. Additional security may be obtained by throwing another ligature round the whole pedicle. The ends of the ligatures are cut off short. A large tenaculum is passed through the pedicle just above the ligature, and the mass is then detached. The stump is held in view long enough to see that there is no oozing from it. It is well to sear it with the actual cautery before dropping it back. This is not essential, but it is a good antiseptic and hæmostatic precaution. The ovary on the opposite side is then to be carefully examined, and, if cystic or otherwise diseased, it is removed, the pedicle being treated in the same way as that of the cyst. During the manipulations above described, pressure is kept up on the abdominal walls, both to prevent the entrance of air and to assist in the expulsion of the tumor.

During the operation the abdomen and the wound are to be kept carefully guarded against cold, and therefore the use of the spray upon or over the patient is objectionable.

It has been supposed thus far that the tumor was one that could be easily evacuated and collapsed. In case it should be found to have solid or semi-solid portions, as

frequently happens, the incision must be enlarged sufficiently to allow of its extraction. It is better to do this gradually, as it is desirable to make the wound no longer than is necessary. Portions which are semi-solid can then be broken up and evacuated by the hand. The extent of the attachments may be ascertained at the same time, and may sometimes be separated in whole or in part. It is better, if possible, not to pass the same hand into the peritoneal cavity afterward; but, in case it can not be avoided, the hand is first washed in the bichloride solution, which the nurse should always have ready for the purpose. There is room for the exercise of much judgment and caution in the separation of adhesions, but there is little time for deliberation. It is very seldom necessary to use any cutting instrument for the purpose, gentle traction being generally sufficient. Particular attention must be given to any bleeding points, which ought to be secured as they appear. The greatest care must be taken to avoid injuring the intestines by the use of too much force. The omental attachments are sometimes extensive, and the injured omentum is so prone to bleed that it is well to ligate and excise any portions that may be wounded. I prefer silk to catgut for this purpose, and also for securing small bleeding points in the abdominal cavity. There is often troublesome oozing from surfaces that can not be reached or tied. This may be checked by steady pressure with a sponge squeezed nearly dry. If portions of the sac are left, and incline to bleed, the use of Paquelin's cautery, at a dull heat, will be found efficient. In other cases a curved needle may be used to include in a ligature the tissue that surrounds the bleeding point. The abdominal wound should never be closed while any considerable bleeding continues. A cylindrical speculum, of large size, is sometimes useful in searching for deep-seated hæmorrhage. Oozing surfaces will sometimes become dry if left at rest for a few minutes. Constant sponging is to be avoided, as it tends to keep the small vessels open and does no good. The sponges used in the cavity must be carefully guarded from contact with the contents of the cyst, and should be kept and washed in a vessel by themselves. In cases where portions of the cyst-wall are left attached, or where the torn surfaces are extensive, or when hæmorrhage is feared, it may be advisable to put in a glass drainage-tube and close the abdominal wound around it. This gives exit to serous or bloody fluid that might cause trouble by decomposing if confined in the cavity; but the drainage-tube is rarely necessary, and is not used nearly so often as it was before the era of antiseptics. It is, doubtless, a source of some danger, and is to be resorted to only in extreme cases. The rule is to close the abdominal cavity hermetically immediately after the operation.

There is a class of cases, not very rare, in which it is evident to the operator that the adhesions are so firm and extensive as to render the removal of the sac utterly impossible, though its contents can be thoroughly evacuated. In these cases the free portion of the sac, if any, is drawn out of the wound and excised, and the edges are so secured by wire or silk in the edges of the wound that the peritoneal cavity is perfectly closed and the cavity of the sac left open, so that it can be easily and thoroughly drained and irrigated

by means of Thomas's double drainage-tube. To one end of the horizontal part of the tube a Davidson's syringe is attached, and to the other a piece of rubber tubing for the escape. It is thus a simple matter to keep the sac washed out as often as may be necessary without disturbing the dressings or soiling them. The tubes are closed by a stop-cock, or by pinching at each side, in the intervals, so that the cavity of the sac is kept constantly full of whatever disinfectant fluid is used. The details of this procedure are so simple that they may be intrusted to any intelligent nurse. My experience in such cases has been with carbolic acid only. The cavity usually diminishes rapidly in size, and either disappears or leaves a small sinus. The large tube is removed as soon as the contraction renders it necessary. A smaller or shorter tube may be used to replace the one removed, but a double tube is not necessary, and a roll of iodoform gauze is commonly sufficient, the wound being syringed out several times daily.

Avoid all unnecessary handling and sponging of the intestines, and if they protrude keep them carefully covered with a hot towel or sponge. All bleeding having ceased, proceed at once to close the wound. The method I adopt is to pass one silver wire, or two if the wound be long, entirely through the abdominal wall, including the peritonæum, and, before tightening these, to close the edges of the peritonæum by a continuous suture of catgut. I then close the remainder of the wound by silk sutures carried carefully through the skin, muscles, and fasciæ, down to the peritonæum, but not through it. The silver sutures are then tightened, and afterward the silk. For introducing the silver wire nothing is better than a common straight sewing-needle, carrying a loop of linen thread, to which the wire is attached. I have the points of the needles ground obliquely, like those of the hypodermic-needle. The same method answers for the silk sutures, or the silk may be carried directly through by the needle. The frequency of mural abscesses after laparotomy shows that too great care can not be taken in closing the abdominal wound. If necessary, a few superficial sutures of fine silk are used to bring the edges nicely together. A narrow strip of iodoform gauze is placed directly over the wound, and the whole is covered with strips of rubber adhesive plaster, laid on transversely, each one slightly overlapping the other. Over this is laid a fold of iodoform gauze and a mass of absorbent cotton. A bandage is then applied firmly around the body and the patient transferred immediately to the bed, which has been previously warmed by hot-water bottles. If the patient is at all weak, it is better to have no pillow at first, and to raise the foot of the bed a little. The administration of ten minims of Magendie's solution immediately after the operation tends to prevent vomiting, and commonly insures three or four hours' sleep. Morphine is administered afterward as may be required to relieve pain or restlessness, and is often the best means of relieving nausea.

After-treatment.—After the operation the patient should be kept perfectly quiet. No one but the doctor or nurse should enter her room, all efforts at talking or thinking on her part should be discouraged, and the room should be darkened, to favor sleep. The patient during the first week

should be kept in a state of vegetable tranquillity. If she is doing well, no friend or relative should be allowed to see her for a week. No food whatever is to be given for the first twelve hours, nor any drink. If the mouth is dry, a very little ice may be given, but even that will sometimes provoke the nausea it is important to avoid. The first food should consist of milk and lime-water, or milk and Vichy water, in equal parts, and not more than half an ounce should be given at a time. That quantity may be given every hour if it is retained; if it is not retained, it is better to wait a few hours and to begin again with a smaller quantity. If the patient is very weak, brandy and water may be substituted for the milk, or brandy may be given with the milk. The error is often made of feeding too early and too often; and it is safer to err on the other side. If, however, the patient has been much exhausted by the operation, it is well to give an enema of beef-juice and brandy soon after she is put to bed, and to repeat it every three hours. In many cases it is well to nourish in this way after the first twelve hours; and if the patient is weak ten grains of quinine should be added to the enema twice a day. If the stomach rejects food in *any* quantity, nourishment by the rectum may be safely relied upon for several days. For this purpose I know of nothing so good as the scraped pulp of raw beef, to which one fourth part of pancreatic emulsion is added, the whole being warmed by standing in a vessel of boiling water until it assumes a homogeneous appearance like that of chocolate. With absolute rest the stomach will generally recover within twenty-four hours. The urine should be drawn with a soft-rubber catheter as often as may be necessary, and with the least possible disturbance to the patient. The temperature need not be taken for six hours after the operation, and, if at the end of twelve hours it has risen above 101° in the mouth or axilla, the dressings are to be removed down to the plaster, and the abdominal coil of rubber or lead applied. A stream of cold water passes continually through the coil, which is kept in action until the temperature falls below 100°. The coil is not then removed, but the flow of water through it is stopped by closing the end of the tube by which it escapes. The cooling process can then be resumed at a moment's notice without even waking the patient. When the coil is once in place I am accustomed to leave it there until the temperature is uniformly low. In case the temperature does not readily yield under the application of cold to the abdomen, the head-coil should be applied also. If these means do not prove sufficient, as they may not in very bad cases, the patient should be transferred to a Kibbee's cot, which allows of thorough douching of the whole trunk, and is by far the most effectual method of refrigeration at our command.

The fever-cot of Dr. Kibbee was first used in the peritonitis following ovariectomy by Dr. Thomas in the Woman's Hospital in 1876. From that time to the present, refrigeration in some form has been used in nearly all cases in that hospital where a rise of temperature occurred after operations of any kind. The results have been highly satisfactory, and many patients have undoubtedly been saved by this means.

The temperature is taken at stated intervals, and the

nurse is not allowed to take it unless directed to do so. It is a useless zeal on the part of some nurses that leads them to concentrate their energies on the temperature and pulse, so that the unfortunate patient is annoyed, every half-hour or oftener, by having the thermometer placed in the vagina or rectum, and the pulse deliberately counted and recounted by the watch; and all this when the patient is doing perfectly well.

It is desirable that the temperature be taken always in the same place for a given patient, and the mouth or the axilla is to be preferred, as causing less disturbance and giving indications sufficiently exact to serve as a warning. In exceptional cases, or when the patient is not doing well, it is advisable to take the temperature in the vagina. On no account should the temperature or pulse be mentioned or discussed within hearing of the patient. Everything that interests or disturbs her is to be studiously avoided. If she is doing well, the temperature need not be taken oftener than once in six hours. Before the bowels have been moved there is often much distress from distension of the intestines with gas. This annoying symptom occurs independently of any threatening of peritonitis. It may be greatly relieved by the introduction into the rectum of a large flexible male catheter, which may be allowed to remain there for several hours. It will frequently bring away a large quantity of wind, and thus remedy the distension of the abdomen.

On the eighth day after the operation all the sutures are removed from the abdominal wound. A few strips of plaster are applied to prevent any strain on the wound. As a rule, if the precautions recommended are carefully observed, union takes place perfectly by first intention.

The bowels should be moved gently within the first week, preferably by injections of olive-oil, followed after two or three hours by warm water. A mild cathartic may be given safely, but is not generally necessary.

During the second week the patient is to be kept as quiet as possible, but the diet is gradually increased, and small quantities of solid food may be given. Not until the end of the third week should the patient be allowed to sit up. After that time convalescence is fully established, and with ordinary care no unfavorable symptoms are to be feared.

The conduct of cases which do well from the beginning is sufficiently simple. Bad cases require so many modifications of the after-treatment, that their management, with reports of complicated operations, will be made the subject of a separate paper.

A STARCH INJECTION MASS.

By SIMON H. GAGE,

ASSISTANT PROFESSOR OF PHYSIOLOGY AND LECTURER ON MICROSCOPICAL TECHNOLOGY IN CORNELL UNIVERSITY.

A COARSE injection mass which is cold-flowing, may be forced nearly to the capillaries, rapidly hardens after injection, leaves the vessels flexible, does not dull dissecting instruments, is suitable for permanent dry or alcoholic preparations, is simple in its manipulation, cleanly and economical, seems to be fully realized in the starch mass introduced by Ad. Pansch, of Kiel, and since recommended, with various

modifications, by Wikszemski, Dalla Rosa, Meyer, and Browning.*

As starch is insoluble in alcohol and cold water, it becomes hard when injected into the blood-vessels simply by the exudation of the liquid with which it is mixed. (That the starch grains forming the mass remain entirely unchanged may be easily demonstrated by making a microscopic examination of the contents of an injected vessel.)

The mass originally recommended by Pansch consisted of wheat-flour and cold water, to which was added a sufficient quantity of the desired coloring matter. Later experiments have shown that pure starch is better than flour.

Mass for ordinary injections:

Starch ("laundry" is good), 1 volume; 2.5-per-cent. aqueous solution of chloral hydrate, 1 volume; 95-per-cent. alcohol, $\frac{1}{2}$ volume; coloring matter (see below), $\frac{1}{4}$ volume.

Since almost any animal injected may afford some organ worth preserving, it seems better to employ permanent colors for tingeing the mass. Among those which are available, probably vermilion, red lead, ultramarine, chrome orange, yellow, or green, are preferable. The color is prepared as follows: Dry color, glycerin, 95-per-cent. alcohol, equal volumes. To avoid lumps, which would clog the cannulæ, or small vessels, the color is thoroughly ground with the liquid in a mortar. It is stored in a well-stoppered bottle, and is prepared for use simply by shaking.

For the injection of brains, and, perhaps, for other rapidly perishing specimens, it seems best, as suggested by Professor Wilder, to use strong preservatives in preparing the mass: Starch (preferably in the form of flour, like the corn-starch used for food), 1 volume; 95-per-cent. alcohol, $\frac{2}{3}$ vol.; 5-per-cent. aqueous solution of chloral hydrate, $\frac{1}{2}$ vol.; coloring mixture (see above), $\frac{1}{4}$ vol.

For convenience and economy, a considerable quantity of either of the masses described above may be prepared at once, and kept in a wide-mouthed specimen or fruit jar. A smooth stick in each jar is convenient for stirring the mass, which should always be done just before using. The syringe may be filled directly from the jar, and any mass remaining in the syringe after the injection is finished may be returned to the jar.

If it is desired to have the mass enter very fine vessels, some of the stock mass, as given above, diluted with an equal volume of water or chloral solution, may be injected first, and immediately followed by the undiluted mass, or, for large animals, a mass containing twice the usual amount of starch. In whatever form the starch is used, it is necessary to work somewhat expeditiously, because the exudation of the liquid in the smaller vessels takes place so rapidly that the mass hardens very quickly in them. The larger the vessel, the more slowly, of course, do the exudation and,

* See Ad. Pansch, "Archiv für Anatomie und Entwickl.," 1877, pp. 480-482, and 1881, pp. 76-78; Wikszemski, same journal, 1880, pp. 232-234; Dalla Rosa, same, pp. 371-377; Herm. von Meyer, same, 1882, pp. 60, 61, and, 1883, pp. 265, 266; Browning, "Annals of Anatomy and Surgery," 1884, p. 24, 25.

† The chloral and alcohol prevent fermentation in the mass when it is kept in stock; the alcohol also increases the fluidity and likewise the more rapid hardening in the vessels; both, of course, act as a preservative upon the animal injected.

consequently, the hardening take place. It sometimes happens that large vessels, like the aorta, are not fully distended after the exudation of the liquid. In this case some mass containing double the ordinary amount of starch can be advantageously injected in two hours or longer after the first injection.

Finally, if vessels injected with the starch mass are dissected free, soaked a day or two in Wickersheimer's preservative, and then dried, they retain their form, and, to a great degree, their flexibility.

ITHACA, N. Y., April 25, 1884.

ABSCESSSES OF THE ABDOMINAL WALL.

By JOSEPH S. CARREAU, M.D.,

VISITING GYNÆCOLOGIST, NEW YORK DISPENSARY; ASSISTANT GYNÆCOLOGIST, NEW YORK POLYCLINIC.

ON account of the scarcity of the literature on this subject, and the rarity of such cases, I bring forward the three following cases. But, previous to doing so, I think it is well to give, in an index form, what has been written on this subject.

Ætiology.—The principal causes are injury, inflammatory diseases of the intestines, inflammation of the muscles, as in fever, decomposition of fatty secretion around the umbilicus, and sometimes they might arise from unknown causes.

Location of the Phlegmon, or Abscess.—The plastic material may be collected in the cellular tissue under the skin; between the layers of the different muscles; between the muscles and peritonæum.

Symptoms.—They are those of all phlegmonous inflammation, although the premonitory symptoms are not well marked, the pain and general disturbance coming on later in the disease, after the process of softening has taken place. Fluctuation is sometimes not easy to perceive, on account of the want of resistance of the abdominal wall. The redness of the skin is only a symptom of superficial abscess of the abdominal wall.

Termination.—It varies according to the location of the disease. If the abscess is subcutaneous it will open on the skin. If it is localized in the meshes of the muscles, it will open on the peritoneal side or on the skin. If subperitoneal, it will either open in the peritoneal cavity and be fatal, or it might produce some adherence between the abdominal wall and the bladder or intestines and open itself in one of these organs; then the prognosis is somewhat favorable.

Diagnosis.—Before the softening process has taken place, the mass is indurated, painless, circumscribed, and can be lifted up with the wall of the abdomen. After the process of softening, occurrence of rigor, with more or less pain at the spot, and sometimes well-marked fluctuation.

Treatment.—Endeavor to promote absorption of the plastic material before the process of softening has begun, but, as soon as pus has been found, it should be removed.

CASE I. *Subperitoneal Abscess.*—MRS. A., aged thirty-two. Married ten years, had four children, youngest three years old. Was well until September, 1882, when taken sick to bed with dysentery; was sent to Charity Hospital, and was discharged the

last of October, although not perfectly well, suffering yet from diarrhœa, fever, and pain in left hypogastric region. In November she came to the New York Dispensary complaining of the above-described symptoms. Then physical exploration was made, and a mass was felt in the left hypogastric region the size of a goose-egg, very tender to the touch, movable under the wall of the abdomen, and giving a sense of fluctuation. The pain was slightly increased by walking, but the mass did not hinder in any way the movements of the lower extremities. She had then a temperature of 103°; dry tongue. The patient was put to bed; an exploratory puncture was made, when half an ounce of pus came out from the mass. On account of the mobility of the mass, that it did not interfere with the movements of the lower extremities, and that nothing was felt in the lower part of the iliac fossa by conjoined manipulation, the mass being situated near the anterior-superior spinous process of the ileum, and could be lifted up with the wall of the abdomen, I concluded that it was in the wall of the abdomen, and probably between the muscles and peritonæum. The condition of the patient becoming alarming, I made an opening two inches in length, when fully half a pint of healthy pus came out. The cavity was washed out with carbolized water, filled with cotton saturated with a 20-per-cent. solution of carbolic acid, and covered with rubber cloth. The patient was doing well under this treatment, but, on account of the difficult removal and reintroduction of the cotton plug, the cavity being over two inches in depth, I had to substitute for the cotton a drainage-tube, which was changed twice a week only, but the patient washing out the cavity through the tube by means of a fountain-syringe. This was kept on, with very little variation, until January, 1883, when all discharge stopped and the opening closed.

CASE II. *Traumatic Abscess of the Abdominal Wall.*—In July, 1883, Dr. John T. Nagle referred to me a young lady, aged sixteen, in perfect health till May, when she received an accidental injury on the lower portion of the abdomen. From that time till August her general health was as good as ever, but she felt that lacing would make her feel uncomfortable, and at about the same time she noticed a scanty purulent discharge from the umbilicus, which the usual domestic remedy had not benefited. Examination showed a papillary growth of soft consistence, bleeding at the least touch, of the color and size of a small strawberry, with an expanded base protruding from the center of the navel and bathed with purulent matter. At the inner side of the papilla a small opening was found extending backward and downward through the mass, at the depth of three inches. In the wall of the abdomen an oblong mass was also felt, extending four inches below the umbilicus, two and a half inches in width, which could be lifted up and moved around with the wall of the abdomen. During all the month of August astringent lotion was injected through the opening and applied externally. Finding no decided local improvement, Dr. C. C. Lee was called in consultation, and found the condition as described (September). Discovering no vesical symptoms whatever, the case was diagnosed as being probably a traumatic abscess of the abdominal wall, with an opening at the umbilicus, and it was proposed to dilate the opening with tents, introduce a drainage-tube, and wash out the cavity twice a day. The umbilicus was dilated to No. 20 American scale, and very little pus was seen, but the patient felt very well for a few days, when inflammatory symptoms appeared, characterized by acute pain localized to the mass, high fever, ranging from 102° to 105°, and vomiting. During that time the tube had to be taken out, a poultice applied over the abdomen, and quinine and morphine given internally to subdue the pain and lower the temperature. After all inflammatory symptoms had disappeared, the drainage-tube was reintroduced; then quite a quantity of purulent matter came

out through the tube. At the time of the consultation the possible non-closure of the urachus was spoken of; but, on account of the absence of all characteristic symptoms of such a disease, it was not thought it could be it. Up to February the treatment has been kept on, and the result has been as follows: The papillary growth has disappeared, the purulent discharge has very much diminished, the mass which was felt from the outside has mostly disappeared, but the opening remains of the same depth; the general health is good, the patient being able to go out. By advice of Dr. Lee, Dr. H. B. Sands was consulted about the case, and diagnosed it as being an abscess of the abdominal wall, after having considered the possibility of a non-closed urachus and a dermoid cyst of the abdominal wall. Dr. Sands thought that the only sure curative treatment would be either a counter-puncture or the slitting off of the canal through, but was in favor of the first. On account of the marked improvement, constitutionally and locally, Dr. Lee, although in favor of the operation, advised a further trial of the treatment.

CASE III. Abscess of the Abdominal Wall following Typhoid Fever.—At the beginning of April, 1883, Mrs. C., aged thirty-seven, had typhoid fever, and was treated in rooms on the top floor of a large dry-goods house. She kept to bed during seven weeks, and was after able to attend to her family duties, but had constant pain at the umbilical region. June 15, 1883, she came to the New York Dispensary, and, on examination, a circumscribed mass, three inches wide, extending from the umbilicus to the pubis, movable with the wall of the abdomen and giving to the hand distinct fluctuation, was found. There was profuse and offensive discharge from the umbilicus, which was very patulous, allowing the introduction of a female catheter to the depth of two inches and a half. Her general condition was very bad; temperature 104° , pulse 138; dry, coated tongue. After two days, having found no improvement from the washing out of the cavity, I made a counter-opening four inches below the umbilicus, washed out the fistulous tract and passed a drainage-tube from one opening to the other, and kept up an almost constant stream of carbolized water. From the puncture one pint and a half of ichorous pus came out, of a very offensive odor. This treatment was kept on, with some slight variations unnecessary to mention here, until the last part of November, when the opening was at last found closed.

NOTES OF PRACTICE.

By C. C. P. CLARK, M.D.,

OSWEGO, N. Y.

Most of us old doctors, in some particulars of practice, follow methods which we know for certain to be sound and valuable, but which are neither generally taught, if at all, in books or schools, nor generally followed, or even known of, by the profession at large. Some of these are borrowed from the wayside, and some are the suggestions of original wit. However derived, to go to our graves without putting them on record is to leave important truths to perish with us, and thus somewhat fail in duty to the generations.

In the little examples of my own conceit in this regard which follow, I shall follow no order of specification, but shall present the several topics as they chance to occur to my mind. Two or three of them I have written about before in the pages of one medical journal or another, but none of them shall be discoursed upon here at such length as to be tiresome, I trust, even for the reader to whom they may not be new.

Treatment of Varicocele.—Books and teachers of surgery constantly or customarily warn us not to mistake a varicocele for a hernia, and aggravate it by the employment of a truss. Now, the fact is that the best of all treatment for this wearing and wearying affection is a weakish truss. It has never failed in my hands, and I have used it scores of times, not only entirely or greatly to relieve the sufferer, but, by continued application, to effect a permanent cure, save in very aggravated cases. The theory of its operation is that, pressing upon the spermatic veins, the pad takes the place of the deficient valves, supporting the superincumbent column of blood which their defection has let weigh wearily down upon the sensitive parts below. This particular of practice is the more important because the ailment is one that makes a man "feel bad all over," and argues to the mind of the patient, and not seldom of his surgeon, a variety of diseases that have no existence. When the bars of honor in our profession are still farther let down, and the "go-as-you-please" principle becomes our law, I propose to advertise a list of the cases of Bright's disease, heart disease, dyspepsia, hypochondriasis—in fact, almost everything but retroflexion of the womb and fissure of its os—that I have cured by the gentle pressure of a truss on the spermatic veins where they pass over the pubic bone. I was my own first case.

Powdered Rhubarb in Certain Ulcerations.—A good many years ago I was requested by a very capable neighboring practitioner to assist him in the ablation of a woman's big-toe nails. I found them imbedded in villainous-looking ulcerations, which had resisted long and various treatment, and, by their torments, had brought the sufferer to consent even to mutilation. I took the doctor aside and told him that rhubarb sprinkled thick in the sores twice a day would cure them in two weeks. And it did. Except when a part of a deformed nail is plunged like a horn in among the granulations and must first be cut away, this treatment of ulcers of the nails is all-sufficient. There are many other superficial ulcerations of the indolent-irritable sort, such as those of stumps, over varicose veins, and so on, in which this remedy is more effective than any other I have ever used or seen used. But it may be that iodoform deserves to supplant it. I learned it of my father, in whose mother-wit I believe it originated.

Chlorate of Potash a Specific in Tinea Tarsi and Porrigo Favosa.—I once had a bad case of tinea tarsi in a little girl in whom I was greatly interested. In spite of the treatment recommended in books in all its variety, the morbid condition of the Meibomian glands persisted in pouring out their sticky exudation, and the continued loss of the eyelashes threatened seriously to disfigure the young beauty. Considering its efficacy when internally exhibited as an alternative in certain affections of the mucous membranes, particularly of the mouth and throat, I gave the patient full doses of this medicine—about a drachm per diem. It worked like a charm. Repeatedly the disease returned, as is its wont, and was as often and as readily subdued, and now the patient's eyelashes—she is since grown to womanhood—are like the drooping and seductive sprays of the weeping willow. I have constantly used this medicine since in that

complaint, and have never been disappointed. Only in addition, the sticky oozing got rid of, red precipitate ointment may be used to be rubbed on the edges of the eyelids night and morning.

Not long after a lad was brought to me whose scalp was thickly bossed with huge stinking, porriginous scabs. Reasoning from what I saw in the last-mentioned case, I used the same remedy to stay the morbid secretion in this, and with like good effect. The crusty hummocks disappeared, as a syphilitic node sometimes will under the use of the iodide of potash, only far more rapidly. He who tries this remedy in this disease in full doses will not turn again to the scalp-shaving, poulticing, etc., which are the customary practice.

Iodine in Acute Lichen and Urticaria.—Failing by various other medicines to benefit a patient who was subject to frequent attacks of acute lichen with most intolerable itching, I gave him the compound tincture of iodine. It proved a speedy cure, as it constantly has in other cases since. The same is true with urticaria, a resembling and probably allied affection. In prurigo and the like itchments of the skin it shows no such virtue. I remember that my wandering mind took the hint of this treatment from the reputed efficacy of this medicine in snake bites, which hardly cause a more rapid serous engorgement than we sometimes see in urticaria.

The same is the best treatment I know of in acne simplex—pest of youthful comeliness—when aided by a calomel ointment. But it is not masterful.

In *Erythema Nodosum*, a rare complaint, but well worthy of consideration, on account of its extreme painfulness sometimes, I have learned to throw over "baths, mild aperients, the abstraction of a small quantity of blood" (Bulkley), and the like stereotyped treatment, having found it readily to yield to the internal administration of the muriated tincture of iron in full doses.

Opium in Bronchocele.—Noticing the great efficacy of opium as an adjuvant to iodide of potash in the treatment of bronchocele with exophthalmos, I thought to try it in the uncomplicated form of that disease, and have found it of such value that I never treat its acute progressive or formative stage without the help of that great medicine, giving perhaps one grain a day.

Liquor ferri subsulphatis in Diphtheria.—While struggling in vain, now above twenty years ago, against the great fatality of this disease, as much a stranger to our observation at that time as the plague, I accidentally learned that Dr. Medina Preston, of Sangerfield, Oneida County, N. Y., where the complaint was also then epidemic, was having very great success in treating it by the local application of Monsel's salt. This medicament was as much unknown to me by that name or for any such use as the disease itself. I procured some of it, and, instructed by Dr. Preston in the method of its use, put it on trial. Since that time I have used nothing else as a local application, and have come to consider it not only as almost sovereign, when timely and suitably applied, but as, in fact, the only thing I know of that has any certain efficacy, topical or constitutional, in the treatment of that complaint. Diluted with water to one half

strength, it is to be well painted twice a day over the diphtheritic patch and the surrounding mucous membrane with a camel's-hair brush, or fine, soft swab. You must get a full, quiet, and continued exposure of the parts, so as to do a good job; to do which the patient, if a child, must be firmly held. To daub the medicine somewhere into the back part of the mouth or down the gullet will by no means answer. This salt is in no way a caustic, nor any disinfectant, nor even, so far as I know, a poison to bacilli or any other such bugbears. But it is a mighty astringent, and seems to operate in the silly way of puckering the life out of the diphtheritic deposit and sucking or squeezing the bad juices out of the living parts adjacent. Not but that the patch or patches of false membrane are apt, notwithstanding, to reappear even again and again, and not seldom with enlarged area, but always with less density and diminished rankness of look. Unfortunately, there seems to be no safe way of effectually applying this remedy within the larynx, so that it is of no use when the disease has invaded that part. Neither dare I claim it to be a specific, but only that it is a very good thing.

Phlyctenular Corneitis has the poison of fever and ague at the bottom, the vesicles on the cornea being identical with the eczema, or "cold-sore," which we so often see on or near the lip in evident intermittents. Accordingly, as many outside of the fraternity of oculists have discovered, though seemingly few within, quinine is the grand remedy, the more effective the earlier employed. The attending photophobia is charmingly controlled by wiping the moistened outside surface of the upper eyelid with a stick of the nitrate of silver till a good smarting is produced.

Epistaxis not dependent on Organic Disease wants a dose or two of blue-pill, or other mild and moderate mercurial.

Nocturnal Spermatorrhoea and Incontinence of Urine commonly get the most help that I have been able to give from a small dose of opium at night, or the like sedative influence of a full dose of ergot.

A Fly Blister more often does good, laid in front of the duodenum, than all the other remedies that I have tried in common attacks of jaundice—I mean those that do not depend on organic disease anywhere. In these cases a tenderness will almost always be discovered over the region mentioned.

Capsicum in plentiful doses, say a drachm or so, has a wonderful control over delirium tremens, pure and simple, in the beginning. Waiting longer, we may as well wait for Nature's own restoration of the over-stimulated sensibility. But most cases of so-called delirium tremens are immediately connected with disorder or distress of some organ or function, and only mediately with strong drink, though strong drink was most likely the original promoter of the whole.

The persistent and distressing giddiness of which now and then a patient otherwise apparently well complains is successfully treated by the

Compound Tincture of Bark. I do not here mean the form of this complaint that suddenly knocks a man down and keeps him for a time disabled. I know no good prescription for this but patience, which after a while will always

justify the prescriber. The *rationale* of both of these forms of vertigo is still a mystery.

Phlegmasia Dolens, now recognized as a simple phlebitis, is effectually controlled and speedily cured by opium, conjoined with a little calomel or other mercurial, which makes superfluous the fomentations, bandaging, blisters, etc., that are commonly resorted to. It should be given to the point of making the patient quite comfortable. This was taught me by Dr. William O'Gorman, now of Newark, N. J.

When a mother's milk is to be dried up, nothing whatever is needed for her comfort or her safety but to leave Nature to herself, and this whether with the recently parturient or after prolonged lactation. This method was used by the late Dr. Hawley, of Hartford, Conn. It is also safely practiced by the lower tribes of animals, from which we may learn much, if we will.

Infants should never be fed from a bottle, but always from a spoon or cup. This is the only way to keep them from being over-fed, which, with the refusal to them of a free supply of water that idiots still practice, kills three fourths of the hand-fed children that die. Always water should be offered before milk is given, otherwise, to quench thirst and not from hunger, they will drink more of the latter than they can digest, and a bellyful of trouble will ensue.

Milk porridge, well cooked, is a better general diet for the sick than either raw milk—now so much in fashion—or any meat broths. The previous coagulation of the casein lightens the work of the stomach.

The hypodermic injection of morphine has the same control over infantile convulsions that it exercises over eclampsia. Also will it generally prevent an epileptic paroxysm, whenever the near approach of one can be discovered.

OSTEOTOMY FOR ANKYLOSIS AT THE HIP JOINT.*

BY CHARLES T. POORE, M. D.,

SURGEON TO ST. MARY'S FREE HOSPITAL FOR CHILDREN.

DEFORMITIES of the hip joint which may be relieved by an osteotomy may be considered under four heads:

1. After hip-joint disease.
2. After rheumatism.
3. After unreduced dislocation.
4. After fracture united at an angle.

The great majority of deformities of this joint follow coxalgia. There are but few persons who have had suppurative disease of this articulation who recover with motion, and many in whom there has been no sign of abscess, yet the joint remains stiff, with an amount of flexion and adduction which interferes much with locomotion; or there may be some movement at the hip joint, yet, on account of the contraction of the psoas and iliacus and the adductors, the limb is flexed and adducted on the pelvis at an angle too great for easy locomotion. The foot can not be planted firmly on the ground, even with the greatest latitude of mo-

tion in the lumbar vertebrae, the gait being awkward and labored.

An ankylosed hip joint in which the limb is held in a straight line with the long axis of the body is a useful one for walking or standing, but it is more of a deformity in any other position of the body than one flexed at a right angle to the pelvis. In the former case the person can not sit down with any degree of comfort, or put on his shoes, whereas in the latter not only is the sitting posture comfortable, but, by the aid of proper orthopaedic apparatus, locomotion can be performed with considerable facility. It therefore becomes an important question to solve, at what angle an ankylosed hip should be placed so as to be a compromise, as it were, between these two positions, and give the patient the greatest amount of use—that is, easy walking, and comfort in the sitting posture. I think that an angle of 125° with the long axis of the body gives this. This, then, taken as a standard, we are in a position to discuss the question of correcting any marked deviation on either side of this line.

The deformity after hip-joint disease is due: 1. To contraction of the psoas and iliacus, causing flexion and rotation of the limb. 2. To the action of the adductors drawing the limb toward the median line. This adduction is accompanied by tilting of the pelvis upward upon the diseased side in walking, in order to bring the limb on a line with the long axis of the body and prevent it from crossing the sound one. It is a compensatory, not a pathological, position. In the early stage of the disease the apparent shortening is due to this tilting of the pelvis. Afterward, in those cases in which changes take place in the head and acetabulum, there is actual shortening of the limb. The difficulty in walking is not due so much to the shortening and flexion of the limb as to the adduction, whether the limb is ankylosed or not. The characteristic awkward gait of a patient who has recovered from coxalgia, with ankylosis or limited motion, is due to the hitching up of the pelvis on the diseased side at every step, in order to get the limb out of the way of the sound one; and, to accomplish this, the pelvis has to be raised so much in many cases that only the toes are able to touch the ground. Even when the real shortening is slight, as mentioned before, the muscles at fault are the psoas and iliacus and the adductors. And, even when it is attempted to correct the deformity by any operation above the insertion of the former, they will prove an obstacle, and in many cases prevent the limb from being brought into a desirable position. In those cases in which ankylosis does not take place there may be motion in the direction of further flexion, but extension beyond a certain point is impossible. And, although the thigh can be brought down so that the foot can be planted flat on the ground, it is not from any farther extension, but it is accomplished by bending forward of the lumbar portion of the spine and tilting downward of the pelvis, due to shortening of the muscles inserted into the trochanter minor. In this class of cases walking is almost as difficult as when the joint is fixed in the same position when there is much adduction.

Absorption, more or less, of the head and neck of the femur and the higher plane occupied by the trochanter, due

* Read before the New York Surgical Society, May 27, 1884.

partly to the above-mentioned changes and partly to elongation of the acetabulum in its upper and posterior portion, increases in no small degree the deformity and the actual shortening of the limb.

In ankylosis following rheumatic inflammation the condition of the parts is entirely different. The bone is not infiltrated with inflammatory products of low vitality. It may be increased in hardness, but the parts retain their normal relation; the neck is not shortened, the ankylosis is usually bony, and the psoas and iliacus are not so much of an element in causing the deformity. It is due more to position, while in hip-joint disease it is the active contraction of these muscles that causes the flexion. In this disease the limb may be fixed in a straight line with the long axis of the body—a condition seldom, if ever, met with after coxalgia.

In rheumatoid arthritis the joint may be surrounded by irregular bony growths, the head and neck being hard.

Deformities may occur after unreduced dislocation. The dislocation may be traumatic or pathological. The latter may occur during the course of hip disease, but I do not think it is so common as some writers would lead us to suppose. It may occur during the course of some debilitating disease—as typhoid, scarlet fever, or acute rheumatism.

Malposition of the femur after fracture high up has been reported.

In forming an opinion in regard to the advisability of performing an osteotomy for the relief of any deformity at the hip joint, the amount of adduction should be considered more than the flexion. I think we are apt to look more at the latter, while the former is the main hindrance to easy locomotion. I think that a moderately flexed limb with much adduction is more of a real deformity than one flexed at a much greater degree without adduction. In the former case the real shortening—I mean by that the distance that the tilting upward of the pelvis raises the foot from the ground in walking—is often more than double the real difference in length of the two limbs measured from the anterior-superior spine. The object of performing an osteotomy, then, is, first, to correct any adduction of the limb that may exist, and, secondly, to reduce the amount of flexion to an angle of about 125° .

There are three points at which section has been made for the correction of deformities at the hip joint—namely:

Through the neck.

Between the trochanters.

Below the trochanter minor.

The section through the neck, known as Adams's operation, can only be performed when the neck is present. It is, therefore, only applicable to cases of bony ankylosis following rheumatism, and it has been advocated in those cases of recovery from hip-joint disease with bony ankylosis in which there has been but slight destruction of the head. But it is a serious question whether patients with deformity after suppurative coxalgia should ever be submitted to this operation. In the vast majority of cases the section would be made through bone, infiltrated with inflammatory products of low vitality. The incision, to gain access to the

neck, would frequently have to pass through tissues which have been the seat of abscess, and even then, after section, it would be difficult to bring the limb down into a desirable position. It is not applicable to cases where the psoas and iliacus are much shortened, and this condition is found after coxalgia more frequently than after any other disease. Again, the muscles inserted into the trochanter minor, being still attached to the lower fragment, must tend to draw the limb inward.

In regard to operations between the trochanters, the section is made farther from the seat of disease in cases of deformity following suppurative coxalgia. It also permits of the removal of a wedge-shaped piece of bone, if so desired, in cases of marked adduction, yet the point of division is above the insertion of the psoas and iliacus, and the same objection holds good as to Adams's operation. If the object is to obtain motion in addition to the correction of the deformity, there is no question that the nearer the division is made to the axis of motion the better; but useful motion is seldom attained, no matter where the section is made, nor what the method of making it.

Section below the trochanter will prove, I think, the best operation in the vast majority of cases, in that it is below the insertion of the muscles attached to the trochanter minor, it is farther away from the seat of disease in deformities following coxalgia, and there is less danger of displacement inward of the lower fragment. I think that the advantage of making the section below the smaller trochanter is not clearly understood. I have lately had the opportunity to examine the parts removed in two cases following an osteotomy for deformity at the hip joint. In one case the femur was divided between the trochanters; in the other the line of section was oblique from without inward and downward, so as to pass through the middle of the trochanter minor. In the first case recovery had taken place with marked adduction. In the second there is a displacement inward of the lower fragment that may be attributed in part, I think, to the action of the psoas and iliacus, whose attachment had not been entirely freed. After section, extension was applied to the limb, by which the lower portion was brought down. The muscles inserted into the trochanter minor draw the upper portion of the lower fragment inward, and cause a projection in this location. In the first case the adduction may have been due to the same cause, although the adductors must have had considerable influence in drawing the limb toward the median line. In regard to the removal of a V-shaped piece of bone, as advocated by Volkmann, from between the trochanters when there is marked adduction, I do not think that it has any advantage over a simple linear osteotomy. It is true that, if the size of the wedge has been accurately calculated, in correcting the two sides of this V-shaped gap will come into apposition while after a linear section there will be a gap left on the inner aspect of the bone which will have to be filled up with new bone. Theoretically, a cuneiform osteotomy is more liable to be followed by suppurative, but practically, if the wound is properly cared for, this accident should not happen. There is, however, greater danger of a piece of cellular or other tissue being caught between the

fragments after a cuneiform than after a linear section, and causing suppuration, and the former takes more time to perform. I am, therefore, of the opinion that a linear section is much the better, as, the more simple an operation is, the better will be its results.

All efforts to obtain useful motion at the point of section have ultimately failed. In a few cases a movable articulation has been obtained, but in time all motion has been lost. In one case (Barton's) it lasted six years, and in another (Sands's) after two years there was limited motion. In other cases it has only lasted a few months, notwithstanding persistent efforts to prevent consolidation. It would seem that the difficulties attending the formation of a false joint are great, and, even if one is obtained, it is a question if it is of any real advantage to the patient. I think that a stiff limb in a good position will afford the patient more security and easier locomotion than the best false joint in this situation, and that a false point of motion is more of a hindrance than an aid to walking.

The method of performing an osteotomy at the upper end of the femur does not differ from sections of bone in other localities. I see no advantage in a cuneiform section over a linear osteotomy, and I think that division of the femur below the trochanter minor is a better operation, and will yield better results in the vast majority of cases than one above this point. The method I have adopted is to make an incision, about one inch long, down upon the outer aspect of the shaft of the femur, at a point just below the trochanter minor. Then, upon the knife as a guide, pass an osteotome down and divide the bone at *right angles* to its long axis. After the bone has been nearly divided, the osteotome is withdrawn and the section completed by fracturing the remaining portion. Some surgeons divide the tendons of the adductors and the long head of the biceps, and a portion of the tensor vaginæ femoris, and twist the bone in various directions in order to break down any adhesions that may exist and stretch the muscles holding the femur in an abnormal position. Unless the deformity is very marked, I do not think a tenotomy is called for, and I have abandoned all twisting and manipulation of the shaft. After placing a narrow strip of adhesive plaster over the wound, so as to bring its lips into close apposition, but leaving a space on either side of the plaster uncovered, so that any undue accumulation of blood can escape, the parts are dusted over with iodoform, and a small compress is placed over the wound, held in position by another piece of adhesive plaster. A bandage is then lightly applied, and a long splint, extending from the axilla to just above the external malleolus, no attempt being made to correct the abduction or flexion. An extension with six or eight pounds' weight is applied after the patient has been put into bed. It will generally be found that upon the third day the wound has closed. Then the extension is run up to ten or fifteen pounds, according to the age of the patient. This amount of extension will bring the limb down, and in all the cases in which I have tried it it has lowered the pelvis of that side so that the limb is slightly abducted.

After an osteotomy in this locality the patient should not be allowed to sit up in bed, but should be kept as flat

as possible on his back until firm union between the fragments has been established. A plaster-of-Paris splint is not a good dressing after these operations; it does not fix the pelvis well. It soon becomes loose, and admits of motion. It does not permit of the use of an extending apparatus, and there is no opportunity to correct any malposition.

The great leverage exerted by the limb upon the point of division and the narrow space above the point over which the bandage can be applied make it impossible to obtain fixation and control over the position of the lower fragment, so that much of the good position gained in the operating-room is lost from the ability of the patient to flex and adduct the limb to a certain extent. A plaster-of-Paris splint is a good dressing when a limb can be incased some distance above and below the point of fracture, but, when the splint only passes a short distance above this point, deformity will occur. The same holds true, but with much greater force, after an osteotomy in the upper part of the femur to correct a deformity in which there is muscular resistance continually to be overcome.

From a careful examination of the two specimens (Dr. Wharton's and Dr. Moore's) it is evident that the section has not been made at right angles to the long axis of the limb, although both operators supposed that the section was made transverse. This was due, I think, to the fact that the limbs were adducted and the bone was divided at right angles to the body rather than at right angles to the femur. I am satisfied that I have made this mistake, and I think it a point one is apt to overlook, not taking sufficient account of the amount of adduction. From the form of the femur at its upper portion, where osteotomy is usually performed, its lateral being greater than its antero-posterior diameter, there must, in all cases where there is any rotation inward of the limb, after correction be a projection inward of the inner portion of the lower fragment, because a wider portion of the femur is brought into apposition with a narrower.

The accidents following an osteotomy at the upper end of the femur are few. Out of 148 patients, 119 were cured with the limb in a good position. Seventeen died, and in 12 the operation failed, making a mortality of 11.48 per cent. In 33 cases suppuration is reported, and in only 3 is any necrosis mentioned. In 3 cases an Adams's operation did not correct, or the deformity returned, and a section below the trochanter minor was performed with success.

In one case (Post) compression of the femoral vessel, from tilting upward of the upper fragment after a section below the trochanter, occurred. In one severe hæmorrhage came on on the twentieth day after a section through the neck (Servias) from either the femoral or one of its large branches, necessitating a ligation of the femoral. The patient recovered.

Maisonneuve is reported to have divided the sciatic nerve during an operation of section between the trochanters through a large wound.

The percentage of fatal cases mentioned above gives a higher rate of mortality than belongs to the operation as now performed. Many of the operations were performed before experience had demonstrated what class of cases were

proper ones for section. In some the section was made too high, or the patients were subjected to an operation at too early a date after the disease causing the deformity had subsided. Many of the operations were performed through large wounds, and extensive dissections were made to reach the bone.

It is also found that twelve of the fatal cases occurred prior to 1877, and only five after that date, the number of cases being nearly the same in the two periods. Lately Dr. E. M. Moore, of Rochester, has published a case in which he had performed an osteotomy between the trochanters for dislocation of the head of the bone. It was at first displaced on to the dorsum of the ilium, but by manipulation had been thrown above the superior lip of the acetabulum, the trochanter being turned backward. Section was made between the trochanters, and, after bringing the foot into its normal position, an extending weight of fifteen pounds was applied. The result was that the shortening, which before the operation had been two inches and a half, was reduced to one, new bone being deposited between the fragments one inch and a half in length. In one case I have tried to obtain a lengthening, and have succeeded.

Correspondence.

LETTER FROM WASHINGTON.

Local Items.—The Proposed Free Medical College.—The Congressional Committee on Public Health.—The National Sanitary Service.

WASHINGTON, May 26, 1884.

MEDICAL matters of local interest are very few since the adjournment of the American Medical Association. Dr. Billings, of the army, and Dr. Brown, of the navy, are to go as representatives to the International Medical Congress at Copenhagen. Professor Elliott Cones and Professor D. W. Prentiss will also make a transatlantic journey during the summer.

The Georgetown Medical College has issued its thirty-sixth annual Announcement. Lectures will begin September 22d.

In Congress, Senator Call made a voluminous speech in favor of the million-dollar-medical-college scheme, which it is proposed by him to be founded here, with various singular attachments by way of professorships. All the stray waifs of the profession are to be gathered into a single fold, with the "eclectics," the "homœopaths," and the "physio-medicalists" occupying the chief seats at the altar. The impossibility of the passage of the bill is its only redeeming feature. It has been intimated that its inspiration came all the way from Tallahassee, where there is a new-fledged medical college with somewhat similar powers.

The Committee on Public Health at their last meeting agreed upon a report adverse to the bill of the National Board of Health, which proposed the re-establishment of those of the board's powers that expired by limitation in June last. The committee say that they do not think the proposed enlargement of the powers of the board wise or expedient, and they are of opinion that the quarantine service has been satisfactorily managed by the Treasury Department, and that the control of national quarantine and epidemics should "rest where it does now." The committee consider that there is a separate field for the National Board of Health in the investigation of disease, and they accept the secretary's estimate as necessary to serve that purpose, and at the same pay the current expenses of the board, and they therefore recommend an appropriation of \$25,000. The report, however, was not presented to the House on the last committee day, and it is considered doubtful whether it will be presented in time to receive any action at this session. The committee also agreed to recommend an appropriation of \$200,000 as a contingent appropriation to be used as heretofore in case of a threatened or actual epidemic. It is from the balance of the last year's contingent appropriation that the expense of the Gulf Quarantine at Ship Island, the South Atlantic Quarantine at Sapelo Sound, and the Cape Charles Quarantine is defrayed. The friends of the board are, however, bestirring themselves with their accustomed vigor, although the season would appear a little late for violent exercise. A petition in their favor from a State Legislature was presented in the Senate on Friday last, and it is understood that similar ones will follow from other Legislatures, and from "convocations" of sanitary bodies as soon as they can be procured.

NEW YORK, SATURDAY, JUNE 7, 1884.

THE PERILS OF PRESCRIPTIONS.

THE experience of almost any physician who has been engaged in practice for a number of years will doubtless bear us out in the statement that patients' lives are often jeopardized, and occasionally sacrificed, by errors connected with prescriptions, committed either by the prescriber or by the apothecary. On a recent occasion six or seven practitioners found themselves thrown together, and the conversation turned upon this subject, when almost every man in the party remembered instances that had come within either his own experience or his own observation in which great risk had been run. One of these gentlemen had nearly killed one of his own children by ordering ten grains of *pulvis ipecacuanhæ compositus* (under the *pharmacopœia* of 1870) when he meant to order *pulvis jalapæ compositus*. Another had written *hydrargyri bichloridum* by mistake for *hydrargyri chloridum* mite, and in consequence a child was given three powders each of which contained one sixth of a grain of corrosive sublimate. Still another had ordered a mixture containing tincture of aconite together with a certain amount of water, but the apothecary omitted the water, and the patient got teaspoonful doses of the tincture.

Fortunately, none of these cases proved fatal, but the hazards attending the practice of prescription-writing were forcibly impressed upon the minds of all present, and the possibilities of diminishing them were discussed. There is a general idea that, if physicians would keep a stock of drugs, and deal them out themselves, the dangers in question would be in great measure done away with. There are, however, weighty objections to the adoption of this practice as a rule, and on the occasion alluded to two instances were mentioned in which a large dose of morphine was taken by mistake for quinine without the intervention of any prescription—in one of the cases a physician took a dose of morphine from a bottle which he himself had labeled quinine; in the other case a gentleman asked an apothecary to give him a dose of quinine, and received morphine instead, which he took at once. Moreover, along with its risks, there is an element of safety in the prescription, so far as the prescriber himself is concerned, since, in cases in which no error has been committed on his part, it constitutes evidence to that effect.

It is apparent, then, that safety is not to be sought for in a discontinuance of the practice of writing prescriptions, and the question narrows itself down to the possibilities of divesting the practice of its dangers so far as may be. To some extent, errors may be guarded against by always keeping a copy of prescriptions; the mere act of making the copy serves to impress upon the prescriber's mind the need of carefulness, and

the copy itself is a precious reassurance in cases where the prescriber is troubled lest he may have made a mistake. Another precaution of great value is the determination never to write a prescription in haste, or while attending to any other matter at the same time, such as answering the questions which patients are often inconsiderate enough to ask while the prescription is being written. In the case of certain preparations, it would no doubt be of advantage to write the common name of the drug, instead of the elaborate name given in the *pharmacopœia*; and it may be questioned if it would not be better if there were less similarity in the *pharmacopœial* names of drugs of different properties. One is not very likely to write corrosive sublimate or laudanum when he intends to write calomel or paregoric, but the *pharmacopœial* names of these drugs are quite apt to be confounded.

THE PHYSICIANS' MUTUAL AID ASSOCIATION.

SEVERAL times before we have mentioned the undertaking which this association has in hand, and have always found grounds for speaking in terms of commendation, both of the plan and of the way in which the association is carrying it out. Concerning the former, we have so often set it forth that it seems sufficient now to say, in general terms, that it comprises a provision for paying a certain sum to the families of deceased members immediately on proper information having been received by the association as to the fact of death, and, in addition, the payment of allowances from the interest of a permanent fund under certain conditions.

In regard to the manner in which the association seeks to attain the object in view, the steady increase in the amount paid to the families of deceased members speaks more forcibly than anything that we could say. It is but a few years since the amount was only two hundred dollars; at present it is four hundred and seventy-five dollars. Such sums are, to be sure, not much in the way of a provision for one's family, but, as we have heretofore pointed out, a great advantage lies in the promptness with which the payment is made. *Bis dat qui cito dat*, and a little ready money at the death of the head of a family often saves the sacrifice of property interests of considerable magnitude.

Important as the association has already become, its increased usefulness is within the power of the profession to an extent that ought to give it a still more rapid growth in membership, for that is the way in which its capability for good is to be heightened, since the sum paid on a death is determined by the number of members. Men are notoriously negligent in such matters, and have to be brought by personal solicitation to look their duty and their interest in the face. This method has been pursued in a most praiseworthy and effective way by some of the older members of the association, and it is almost wholly to their efforts that the growing prosperity of the organization is due. But the burden should not rest forever on a few individuals; it seems reasonable to think that the general medical societies might properly take more interest in the matter than they have taken heretofore. One of them, indeed, has

accomplished a good deal in this way; we refer to the Medical Society of the County of Kings, which has for several years had a standing committee devoted to auxiliary work in the interest of the association. It seems to us that it would not be in any way improper for others of the larger societies to follow some equivalent course.

MINOR PARAGRAPHS.

THE HARVARD MEDICAL SCHOOL.

LAST October we gave our readers an account of the exercises held on the occasion of the one hundredth anniversary of the foundation of the school. It was a memorable celebration, and one of which the profession in Massachusetts may well feel proud. It is gratifying to find, therefore, that the proceedings have been recorded in permanent form, in a handsome brochure issued from the University Press at Cambridge. It gives the addresses delivered at the celebration, and an appendix is added, written by Dr. Oliver Wendell Holmes, which presents a succinct account of the endowment of the school. As a frontispiece, there is a well-executed woodcut of the new building, and the book is further illustrated by views of the old building in Mason Street, as it appeared in the year 1815, and of the building in North Grove Street, the latter being the structure in which most of the graduates of the college now living pursued their studies. There are few if any achievements on which the medical profession of this country may reflect with more satisfaction than the gradual growth of the Harvard Medical School, and there is abundant reason to feel confident that the career of the school in its new quarters will form the subject of like congratulation to those who may perchance celebrate its future centenaries.

NEWS ITEMS, ETC.

INFECTIOUS DISEASES IN NEW YORK.—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending June 3, 1884:

DISEASES.	Week ending May 27.		Week ending June 3.	
	Cases.	Deaths.	Cases.	Deaths.
Typhus	1	1	3	0
Typhoid Fever	7	2	3	5
Scarlet Fever	76	17	57	9
Cerebro-spinal meningitis	3	3	4	4
Measles	108	21	153	28
Diphtheria	47	23	52	18

AN AMBULANCE SERVICE FOR INFECTIOUS DISEASES has been established in Paris, the use of the vehicles being free to the public.

A QUARANTINE SERVICE ON THE RED SEA is urged by the French medical journals as a precaution against the expected conveyance of cholera into Europe this summer by ships coming through to the Mediterranean by way of the Suez Canal.

THE MEDICAL DEPARTMENT OF THE CENTRAL UNIVERSITY, OF LOUISVILLE, held its annual commencement exercises on Thursday, May 29th, and the degree in medicine was conferred on a class of thirty-one.

COLUMBIA COLLEGE.—We understand that a course of lectures on hygiene and sanitary engineering will be given by Dr. John S. Billings, of the army, next year.

THE COLLEGE OF PHYSICIANS AND SURGEONS.—Dr. Robert F. Weir has been appointed clinical professor of surgery.

THE WOMAN'S MEDICAL COLLEGE OF THE NEW YORK INFIRMARY held its fifteenth annual commencement on Thursday, May 29th, at the University Club Theatre. The degree was conferred on a class of eight ladies.

THE MEDICAL SCHOOL OF MAINE.—It is reported that Dr. Burt G. Wilder has resigned his position of professor of physiology. For the sake of the school, we trust that the report may prove to be erroneous.

THE UNIVERSITY OF PENNSYLVANIA.—It is reported that Dr. Alfred Stillé has resigned the chair of the Theory and Practice of Medicine, and that Dr. William Pepper, Provost of the University, has been elected to fill the vacancy. The chair was formerly occupied by his father, whose namesake he is.

THE WOMAN'S MEDICAL COLLEGE OF THE NEW YORK INFIRMARY.—We understand that Dr. Robert Abbe has been appointed professor of surgery.

THE PRESBYTERIAN HOSPITAL.—Dr. Alfred C. Post has been elected President of the Medical Board.

ST. LUKE'S HOSPITAL.—Dr. Robert Abbe has been appointed one of the surgeons of the hospital, in place of Dr. William T. Bull, resigned.

PROFESSOR GROSS'S WILL is reported to provide that his medical books, diagrams, and specimens shall go to the Jefferson Medical College, the Philadelphia Academy of Surgery, or the College of Physicians of Philadelphia, as the executor may decide, and, in the event of neither of those institutions accepting the bequest, to the University of Pennsylvania or the New York Academy of Medicine, of which latter the testator was an honorary fellow.

THE CITY BOARD OF HEALTH has lately had trouble with the Fire Department, the latter having taken forcible possession of an engine-house which the board had occupied for many years with its chemical and disinfecting appliances. The board has procured an injunction restraining the Fire Department from any further interference with its occupancy of the premises.

A REWARD OF \$100,000 is provided for in a bill recently introduced into the United States Senate, to be given to any person who shall discover the true germ of yellow fever, or any certain way of preventing or materially modifying the spread of the disease.

AN HONORARY DEGREE.—We understand that the degree of LL. D. has been conferred on Dr. Morris H. Henry, of New York.

ARMY INTELLIGENCE.—*Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from May 25, 1884, to May 31, 1884:*

WRIGHT, J. P., Major and Surgeon. Directed to perform, temporarily, in addition to his other duties, those of Medical Director, Department of the Missouri. Par. 2, S. O. 107, Headquarters Department of the Missouri, May 28, 1884.

MIDDLETON, PASSMORE, Captain and Assistant Surgeon. Granted leave of absence for one month on surgeon's certificate of disability. Par. 2, S. O. 107, Headquarters Department of the Missouri, May 28, 1884.

HALL, WILLIAM R., Captain and Assistant Surgeon. Assigned to duty at Fort Stockton, Texas. Par. 1, S. O. 63, Headquarters Department of Texas, May 19, 1884.

BAILY, JOSEPH C., Major and Surgeon, now on leave of absence, is relieved from duty in Department of Texas, and ordered to report to commanding general, Department of the

East, for assignment to duty at Fort Monroe, Virginia, to relieve Lieutenant-Colonel Charles Page, Surgeon, U. S. Army, on July 1, 1884, from duty at that station.

Lieutenant-Colonel Page, on being relieved by Major Bailly, will proceed to Fort Leavenworth, Kansas, and report to commanding general, Department of the Missouri, for assignment to duty as Medical Director of that department. Par. 12, S. O. 125, A. G. O., May 29, 1884.

NAVAL INTELLIGENCE.—*Official List of Changes in the Medical Corps of the Navy during the Week ending May 31, 1884:*

ANDERSON, F., Passed Assistant Surgeon. Ordered to Navy Yard, New York.

BEYER, H. G., Passed Assistant Surgeon. Detached from Coast Survey steamer Blake, and ordered to Smithsonian Institution for special duty.

RUSH, W. H., Passed Assistant Surgeon. Detached from U. S. S. Despatch, and ordered to Coast Survey steamer Blake.

HENEBERGER, L. G., Passed Assistant Surgeon. Detached from Navy Yard, New York, and ordered to U. S. S. Despatch.

GREIFFITH, S. H., Passed Assistant Surgeon. Ordered to U. S. S. Lancaster, on expiration of leave of absence.

JONES, M. D., Passed Assistant Surgeon. Detached from Naval Hospital, New York, and resignation accepted June 15, 1885.

WISE, I. C., Surgeon. Detached from Naval Academy and ordered to U. S. S. Constellation.

SOCIETY MEETINGS FOR THE COMING WEEK.—*Monday, June 9th:* New York Academy of Sciences (Section in Chemistry and Technology); New York Medico-Historical Society (private).

Tuesday, June 10th: Massachusetts Medical Society (Boston—first day); New Jersey State Medical Society (Cape May—first day); New York Medical Union (private); Medical Societies of the Counties of Chemung (annual), Chenango, Genesee (annual), Livingston (annual), Onondaga (annual), Oswego (annual), Rensselaer, St. Lawrence, Schenectady, Steuben (annual), Warren (annual), and Wyoming (annual), N. Y.; Jersey City Pathological Society; Newark, N. J., Medical Association (private); Trenton, N. J., Medical Association (private).

Wednesday, June 11th: Massachusetts Medical Society (second day); New Jersey State Medical Society (second day); Rhode Island Medical Society (Providence); New York Pathological Society; American Microscopical Society of the City of New York; New York Medico-Legal Society; Medical Societies of the Counties of Cayuga (annual), Cortlandt (annual), Delaware (annual), Dutchess, Erie, Montgomery (annual), and Sullivan (annual), N. Y., and Middlesex, N. J. (annual).

Thursday, June 12th: Brooklyn Pathological Society; New York Laryngological Society (private); Society of Medical Jurisprudence and State Medicine; Harlem Medical Association (private).

Friday, June 13th: Medical Society of the Town of Saugerties, N. Y.

Saturday, June 14th: New York Medical and Surgical Society (private).

OBITUARY NOTES.

DR. THOMAS C. CHALMERS died at his residence, No. 25 West Seventeenth Street, on Wednesday evening last, at the age of seventy-four. He was born in West Galway, N. Y., June 10, 1810, received his collegiate education at Union College, and was graduated from the College of Physicians and Surgeons, New York, in 1835. For many years he was connected with the New York Hospital. He was a member of the Medical Society of the County of New York, and of the Academy of

Medicine, of which he was one of the founders. As a physician he was held in high esteem for his skill and devotion to his patients; as a man he was honored for his upright character and for his kind-hearted and benevolent nature.

WILLIAM HUSTACE HUBBARD, M.D.—Dr. Hubbard, one of the internes of the medical staff of Bellevue Hospital, died at the residence of his father, in the city of New York, on Thursday afternoon, May 29, 1884, of typhoid fever. The deceased was the youngest son of Dr. Samuel T. Hubbard and Mary H. Hustace, his wife, and was born in the city of New York, March 24, 1859. His preparatory classical studies were prosecuted under the guidance of Mr. M. W. Lyon, a celebrated teacher of this city, and at seventeen years of age he entered Columbia College. In this institution he graduated in arts with distinguished honor in 1880. Showing a predilection for the medical profession, he at once commenced the study of medicine under the guidance of his distinguished and honored father and Dr. W. H. Porter, and in due time matriculated at the College of Physicians and Surgeons of New York, from which institution he graduated in 1883. During a portion of his term of medical study he was prosector to the distinguished professor of anatomy, Dr. T. T. Sabine. His medical, like his classical, pupillage was characterized by an earnest, faithful, and untiring devotion, and prosecuted with an enthusiasm which resulted in his becoming one of two successful competitors for the vacancy on the assistant medical staff of Bellevue Hospital. He entered upon the duties incident to the appointment in October, 1883. His attainments were of the highest order, and his earnest devotion to the duties incident to the new position challenged the shafts of death. He has fallen an early sacrifice upon the altar of medical science. His death is an ennobling instance of the self-sacrificing virtues of the true practitioner of our time-honored profession. The warmest sympathy of the profession will be extended to the stricken and bereaved father and his family.

P.

Letters to the Editor.

THE STATE SOCIETY'S COMMITTEE ON LEGISLATION.

NEW YORK, May 24, 1884.

To the Editor of the *New York Medical Journal*:

SIR: Permit me through your columns to correct some errors contained in the communication of Dr. Piffard, dated April 17th, a month prior to the publication of my letter.

My letter was written, not for the purpose of criticising the Committee on Legislation of the Medical Society of the State of New York, but the reported remarks made by Dr. Piffard at the adjourned meeting of the county society in April, that it was not the business of the Committee on Legislation to attend to a certain bill then pending before the Legislature. I then held, and still hold, that it is the duty of the committee to attend to such matters, and, inasmuch as it has attended to them, it would seem that Dr. Piffard has become convinced of the correctness of this view of the case. But suppose that I had criticised the non-activity of the committee, I should like to inquire upon what grounds Dr. Piffard considers himself or his acts above criticism? Is he endowed with the divinity that doth hedge a king? Until I am convinced that he is so endowed, I shall continue to criticise his public acts when, where, and how I please.

Dr. Piffard then goes on to say that the expenses of this committee so far do not exceed seventy-five dollars, while the past

committee's expenses amounted to over twelve hundred dollars. The relevancy of this statement to the question at issue is not quite apparent, but I suppose it is meant to show that the former committee's expenses were not warranted. If so, Dr. Piffard is responsible for certifying that those accounts were proper and should be paid, inasmuch as he was one of the Committee of Audit to examine into these accounts. If he does not mean that the expenses were unwarranted, then he is guilty of a piece of shabby inuendo.

While praising the action of the committee in defeating "ten injurious and objectionable medical bills," it does not seem to have occurred to the chairman of this committee that perhaps some of this praise is due other agencies. At any rate, let us hope that this cheap work may not prove as cheap as that wonderful bantling of Dr. Piffard, the law of 1880, most of the provisions of which are either useless or injurious, and which I will readily admit is cheap in quality and dear in price.

The charge of bad taste which Dr. Piffard makes sounds a little odd, and tempts me to offer, for the consideration and guidance of my esteemed colleague, the old adage that the shoemaker should not go beyond his last.

Faithfully yours,

F. R. STURGIS.

* * It was by an error that Dr. Piffard's letter was dated April 17th; it should have been dated May 17th. We think the controversy between Dr. Sturgis and Dr. Piffard has gone as far as its interest to our readers will justify, and we therefore feel compelled to say that, after allowing each of those gentlemen one more opportunity, we must decline to lend our columns to its continuance.

Proceedings of Societies.

NEW YORK ACADEMY OF MEDICINE.

Meeting of June 5, 1884.

The President, FORDYCE BARKER, M. D., LL. D., in the chair.

ADMISSION OF NEW FELLOWS.—Twenty-four new Fellows were admitted to the Academy.

REMARKS BY THE PRESIDENT ON THE LATE DR. WILLARD PARKER AND THE LATE DR. SAMUEL D. GROSS.—After the formal admission of the new Fellows, the President said: Having welcomed each of our new Fellows individually, I assume the privilege of congratulating both them and the Academy on this accession to its numbers and its strength, with the full conviction that the benefit will be reciprocal. We count upon the new Fellows to co-operate with zeal and earnestness "in the cultivation of the science of medicine," and in every good work "for the advancement of the character and honor of the profession," and we can not doubt that every one who has now joined us will find their individual gain and personal advancement in this work. But I will not detain this meeting by repeating truths which must be obvious to all, as otherwise they would not be with us. But, in connection with the death of two of our most distinguished and eminent Fellows, I have become acquainted with certain facts in regard to the history of our Academy which seem to me curious and interesting. The Academy was founded thirty-seven years ago, and the roster published in 1880 gives the names of 118 original Fellows. One hundred of this number are now dead. I find that 7 of this number died between the ages of 80 and 90, the average of these being 83. Eighteen died between the ages of 70 and 80, the

average being 73. Forty-seven died between the ages of 55 and 70, the average being 64.5. Of the 18 still living, a large majority are in vigorous health, and still are in more or less active professional life. Eight of our ex-presidents who were original Fellows have died, the average age of this number at the time of death being 78.5. The other original Fellows who have died ex-presidents were Dr. John Watson, aged 55, and Dr. H. D. Bulkley, aged 67. Dr. James Anderson, now our senior ex-president, has already passed his eighty-sixth birthday, is still as erect as ever and mentally active, and continues his warm interest in the Academy. I am certain that I give expression to the sentiment of all in the prayer that he, with the other Founders of the Academy, may long continue with us.

There must be some explanation of the remarkable longevity of our Founders, which I leave for others to explain. Notwithstanding the hard life of medical men, their incessant toil, the frequent impossibility of regular hours for food and sleep, and their great burden of anxiety and responsibility as to the happiness and life of others, I believe it has been proved that their longevity as a class compares favorably with that of other professions. But this history of the Founders of the Academy seems to be remarkable, and I know not where its parallel can be found in any other class of one hundred and eighteen men who have been brought together without any selection as to their probabilities of long life. May we not ask whether this Academy has not been a factor in bringing about this result? The stimulus of such an association of educated men must have some influence in leading to an active, useful, regular, and honorable life, the incitement to constant mental and physical activity, the interchange of social feeling, the promotion of kindly sympathies and their influence in preventing "envy, hatred, malice, and all uncharitableness"—all those influences which repress those passions and emotions unfavorable to longevity may have really contributed more to this result than a careless superficial observation would suspect.

While all must bear those sorrows and trials which are common to humanity, I can not forbear a reference to a recent loss which has befallen one of our Founders*—who has the respect and warm esteem of all the profession, and who has ever been a zealous and most efficient friend and a most faithful office-bearer in the Academy—by the death of a most promising son, who lost his life by disease contracted in the performance of his duty in Bellevue Hospital. In such a sorrow, it may be some consolation, slight though it be, that his death was glorious, on the field of his early battle with disease, and the assurance that the afflicted parents have the sincere condolence and profound sympathy of all in this Academy.

Within a few weeks the profession of this country have lost two of its best-known and most distinguished men—and both belonged to this Academy. I shall not now repeat any of those biographical details which have been so generally published. I shall only refer to their connection with us, and their personal qualities which seem to explain their great success and eminence in the profession.

Dr. Willard Parker was elected President of this Academy in 1866. At the time of his death he was the senior ex-President, and within a few months of eighty-four years of age. For many years he was the most prominent and conspicuous medical man in this city, not only as a surgeon but as a general practitioner. With the exception of Dr. Benjamin Rush, a hundred years ago, I do not think any physician in this country ever commanded so great a professional and public influence in the community where he resided as Dr. Parker did in this city for many years. His personality, his attractive and commanding

* Dr. Samuel T. Hulbard.

presence, his genial and winning manners, his uniform cheerfulness, his ease and fluency in conversation, his uncommon practical sense—all combined to produce a magnetic influence on all brought in contact with him. The most prominent characteristics of his professional mind were quick perception, a kind of insight which gave him an intuitive power of distinguishing the radical and essential features, from what was merely incidental, coincident, or secondary. In the treatment of his cases I may say that, while I do not think that he could be ranked as a great therapist, he assuredly was exceptionally successful. I think that he always relieved and made his patients feel better. I have never known a physician who more thoroughly appreciated the influence of the *morale* or the *physique*, or more constantly utilized this knowledge in his practice. They all had the stimulating and tonic effect of confidence, cheerfulness, and hope.

Thirty-two years ago I received a note from Dr. Parker, which I still have in my possession, saying that he had a call out of town, and that, as Dr. Sabine was also away, he inclosed a list of a few whom he wished me to visit during his absence. The first was an extremely clever and accomplished lady. As I entered her room, her bed being in such a position that she could not see the door, she said:

"His very foot has music in't
As he comes up the stair."

I introduced myself, saying that the quotation was apt, but misapplied, as there was a great difference between B. and P.

I am very certain that no one ever entered or left his consulting rooms quoting from Dante's "*Inferno*,"

"Who enters here leaves hope behind."

His general and hygienic directions must have been of unusual excellence. Some years ago he gave a popular course of lectures both in this city and in Brooklyn. Although they were meagerly and imperfectly reported, I well remember that I read them carefully, and regarded them as the most useful and sensible popular lectures on health which had appeared since the famous work of Andrew Combe. Of his rank hereafter as a great surgeon I am not competent to speak. Dr. Parker's life was too incessantly occupied in active practice to permit him to contribute very largely to the literature of our profession; but many valuable papers by him were published in the medical journals. I think few can estimate the number of lives which he has been the means of saving by his paper on "*Operation for Abscess of the Appendix Vermiformis*." I speak from a sense of personal gratitude, as I think this paper saved the lives of two of my own patients.

Many notes which I have received from Dr. Parker during the past six years and his presence at every meeting of special interest, so long as his health permitted, warrant me in asserting that he kept up to the last the warmest interest in the Academy of Medicine.

Professor S. D. Gross, whose death occurred last month, in the seventy-ninth year of his age, was elected a Corresponding Fellow of this Academy in 1851, and an Honorary Fellow in 1876. No man of the present age—I assert this without qualification—has made such a reputation as a great surgical teacher and writer. No one of the profession in this country has received such honors from universities and learned societies in Europe, while the profession in this country have heaped upon him the highest honors at their disposal. In regard to him, the voice of envy is never heard, and no one, so far as I have heard, has ever whispered that these honors have not been honestly earned and are well merited. I have never heard a disparaging word as regards his personal or professional character. Underlying all this, I have observed that every one, even those who

had no personal acquaintance with him, seemed always to speak of him with an unconscious coloring of personal regard and affection. This was probably due, in a large measure, to the honesty, sincerity, and integrity of purpose which stamped his personal bearing and were transparent and conspicuous in all his writings.

His industry and ability were marvelous, and the amount of work which he accomplished was monumental. I do not believe that another instance can be found in medical history where a man seventy-eight years of age has written such a paper as that read at the last meeting of the American Medical Association on "*Laceration of the Female Sexual Organs consequent upon Parturition*." In its familiarity with all the recent literature of the subject, its breadth of treatment, and its soundness of teaching, although in some points many would hold different opinions, the most distinguished gynecologist of the present day might feel proud of having written it. Many may not know that one of his early works was a translation of Hatin's "*Manual of Obstetrics*," now rarely met with, but I have now the honor of presenting a copy to the Academy.

The last time Dr. Gross met with us was the evening when this hall was opened. Dr. Acland, Regius Professor of Medicine in Oxford University, in his speech alluded in the warmest terms to Dr. Gross, speaking of him as the senior graduate of Oxford. No one present can forget his appearance when called up by the chair. It was evident that he had not anticipated such a call, but his speech impressed me as the most touching, from its effective simplicity, of any made that evening. It came straight from the heart, dropping with it, as his speeches always did, some suggestive thoughts.

To each of the two men—Willard Parker and Samuel D. Gross—may be applied, with greater truth than it usually is, the trite quotation:

"He was a man, take him for all in all,
I shall not look upon his like again."

Their name and fame are a part of the common inheritance of our Academy. There is no greater inducement to stimulate those who are coming after than the character and success of the great ones who succeed, and therefore it is our privilege as well as our duty to sacredly cherish their memory.

(To be concluded.)

NEW YORK SURGICAL SOCIETY.

Meeting of May 27, 1884.

The President, ROBERT F. WEIR, M. D., in the chair.

OSTEOTOMY FOR ANKYLOSIS AT THE HIP JOINT.—Dr. C. T. POORE read a paper with this title. [See p. 633.]

Dr. A. C. Post said the case referred to by Dr. Poore in his paper was that of a young man upon whom he operated many years ago in the New York Hospital for ankylosis following morbus coxarius which occurred in childhood. He divided the bone and brought the limb down into a good position, and the case seemed to promise well, but within one or two days after the operation the limb became enormously swollen and discolored, and the patient died of gangrene. The operation was performed below the lesser trochanter, and at the autopsy it was found that the gangrene was caused by the hooking of the femoral vessels over the projecting part of the upper segment of bone.

THE PRESIDENT remarked that gangrene after osteotomy at the lower end of the femur had occurred in two cases within the last two years.

Dr. J. C. HUTCHINSON thought that removal of a wedge-shaped

piece of bone was unnecessary, because the osteotome itself made a wedge-shaped opening, and, when the bone was straightened, the opening was closed, and in the operations which he had performed he had found it quite sufficient. He thought that the methods adopted and advised by Dr. Poore were such as were usually approved of by surgeons of the present day. In ankylosis of rheumatic origin, the head and neck of the bone being intact, Adams's operation through the neck should be performed, because, being nearest the center of motion, the formation of a movable joint here allowed more freedom in the movements of the limb. If, however, the rheumatic arthritis was attended with large nodular deposits of new bone around the neck, this operation was inappropriate. The advantages of the operation below the trochanter (Gant's) had been well stated by Dr. Poore, and he thought that all surgeons would agree with the author of the paper that this operation was preferable in strumous cases in which there was more or less destruction of the head of the bone, and a large proportion of cases requiring operation belonged to that class.

He had divided the upper end of the femur three times. In one case both bones were divided simultaneously, and the patient was treated subsequently by simple extension with a weight and pulley. This patient was shown to the Society. In the other case the patient was kept in bed for two weeks only, and extension was made by the weight and pulley. At the end of this time, when the immediate effects of the operation had subsided, he was put upon crutches, the sound limb being elongated by a high shoe so as to suspend the diseased limb and allow it to make extension by its own weight, and also to be moved at the point of section with a view of obtaining a false joint, using the weight and pulley at night. Union, however, took place in this case. The advantages of this method were that the patient was vastly more comfortable, while the weight of the suspended limb gave all the extension necessary, and an artificial joint was most likely to be formed, if this was desirable, than if the patient were kept in bed longer. Dr. Poore was to be congratulated for being able to overcome adduction without resorting to myotomy.

Dr. POORE remarked that the only two cases in which a false joint had remained for a considerable length of time were those reported by Barton, in which motion continued for six years, and the case reported by Dr. Sands, in which motion continued for two years. Dr. Walton, of Pittsburg, in one case divided the bone, as Dr. Sayre did, between the trochanters, and the same history followed—that is, motion for a time, and then an abscess would form and the patient would be worse. After recovering from this somewhat, he would begin with passive motion, and the last record was that the bone at the point of motion was becoming ankylosed. There was no case on record, so far as he had been able to find, in which a permanent false joint had been formed. Dr. Poore thought the fatal cases as a rule followed section of the bone after ankylosis from hip-joint disease. At least this had been the fact within the last twelve years. Previous to that date the operations were done through a very large wound, and he thought that those cases should hardly enter into statistics.

CONGENITAL DEFORMITY OF THE HAND; COMBINED ECTRODACTYLISM AND SYNDACTYLISM.—Dr. Post then read a paper with this title. [It will be published in full next week.]

At the conclusion of the paper Dr. Post remarked that the one most important point in difficult cases was to operate separately upon each individual space. If all were operated upon at once, it sometimes gave rise to serious inflammation, and there was always increased difficulty in applying the dressings.

SARCOMA OF THE LOWER JAW.—Dr. Post presented a specimen, which was interesting especially on account of one point

connected with the operation. The tumor was removed from a girl twenty years of age. The existence of the tumor had been recognized eight months. He divided the jaw-bone through the middle and removed all the swollen part of the jaw, the outer incision extending to the angle, when he found marks of the disease extending farther. He then removed a second, and finally a third segment of bone. After removing the first segment of bone there was rather copious hemorrhage, which came from the inferior maxillary artery, which he plugged with wax. After making the second section of the bone the hemorrhage was profuse, and could not be controlled by means of wax, and he therefore drove a wooden plug into the bone. Afterward he cut above the entrance of the inferior maxillary artery into the bone, and no hemorrhage followed. The laceration of the artery by driving the wooden plug into it had completely arrested the hemorrhage, so that afterward, when the ramus of the bone was divided above the entrance of the artery, there was no trace of hemorrhage.

MYO-FIBROMATA OF THE UTERUS; LAPARO-MYOTOMY.—Dr. L. A. STIMSON presented a uterus, with myo-fibromata attached, which he removed, on the 24th of May, from a colored woman thirty years of age. The patient was sent to him from New Jersey, with a history of a tumor which was first noticed eighteen months ago in the lower portion of the left side of the abdomen, and which caused so much pain and distress that she was unable to earn her living. She was the mother of one child, born ten years ago. On examination, he found a firm, irregular tumor, extending a little from the right of the median line above the pubes upward to the left, and occupying the left iliac fossa to the height of the umbilicus, and it could be felt through the vagina in front of the uterus. The patient was kept under observation for a few days, when it was found that the tumor had changed its position somewhat, and, by exploration of the uterus, it was found to be independent of it, or at least movable upon it. A second tumor, thought to be the uterus, was felt behind and to the right of the main tumor. The diagnosis was that of a pedunculated fibroid of the uterus, with other fibroid growths within the uterus. An operation was undertaken for their removal by making an incision in the linea alba from the umbilicus downward under bichloride irrigation, and after the bleeding had been completely arrested, the peritoneum was divided to an extent sufficient to admit four fingers, when the diagnosis was confirmed by digital examination. The tumor was brought out through the incision, consisting of a mass somewhat heart-shaped, measuring about five inches in its greatest diameter, irregular in outline, with many nodules, and connected with the anterior surface of the uterus by a narrow pedicle. On drawing out the left ovary, it was found that the broad ligament was increased in width and length, and that the ovary was at some distance from the uterus. The ligament was transfixed below the pampiniform plexus with an ivory pin carrying a double silk ligature, and the ovary, with the plexus, was cut off with the tube. Then, bringing the right ovary into sight, it was found so closely attached to the uterus that a ligature could not be safely passed without causing an unfavorable amount of bleeding, and, as the cervix was long and narrow, he decided to remove the entire organ by amputation through the cervix. The uterus was drawn up, the cervix was transfixed with an ivory pin carrying a double silk ligature, by means of which a round rubber cord, about 3 mm. in diameter, was carried and tied upon either side, and the organ with the remaining ovary cut off above. The pedicle was so long that it could be easily brought into the abdominal wound, and was secured in the lower angle with two pins. There was no hemorrhage, except very slight bleeding from the puncture of the cervix by the ivory pin, and, when the operation had been

completed and the sponge was introduced into Douglas's cul-de-sac, it brought away only one small clot about an inch in length and of about the size of a lead-pencil. The peritonæum was united by a continuous catgut suture, as was also the aponeurotic layer. Six silver sutures were then passed about two inches from the edges of the abdominal wound and made fast with buttons. The stem of the pedicle was transfixed with two steel needles resting on the skin and the cutaneous incision closed with a continuous catgut suture. A decalcified-bone drainage-tube was inserted under the skin, from the upper angle of the wound to the pedicle, and the whole was covered with iodiform gauze.

On the next day, as there was some abdominal tenderness, with slight elevation of temperature (101° F.), the dressing was removed and there was found some bloody serum, which was dried, and the wound was dry. He covered the wound with a little gauze kept wet with the bichloride solution and applied the leaden coil, and under that treatment the pain had diminished and the temperature had sunk to 100.25° , and now, on the fourth day after the operation, the patient was apparently out of danger. She had also received a small quantity of morphine, about thirty minims of Magendie's solution in the course of twenty-four hours. [May 31st the patient was doing well.]

COMPOUND FRACTURE OF THE SKULL.—Dr. STIMSON also presented a specimen which showed much more extensive fracture of the inner than of the outer table of the skull. The patient was walking upon the street when a brick fell from a building and struck him upon the right temporal bone about one inch to the outer side of the median line, driving in a portion of the skull to the depth of nearly one inch at the deepest point. The patient remained conscious. On the 24th of May, when Dr. Stimson saw him, three hours after the receipt of the injury, he found a ragged wound of the soft parts, exposing a denuded area of bone, and from the broken edge of the bone there came out a small quantity of brain matter. Dr. Stimson removed the adjacent portion of bone with a rongeur, and was able, after enlarging the opening somewhat, to withdraw the piece of skull presented, of which the outer table was somewhat irregular and perhaps three fourths of an inch in diameter, while the inner table was one inch and a half in diameter. The patient was doing well. The escape of brain matter ceased as soon as pressure was removed.

VESICAL CALCULUS REMOVED BY LITHOLAPAXY.—Dr. STIMSON also presented a specimen of hard phosphatic stone which on the 14th of May he removed from the bladder of a man fifty years of age. The time consumed was about forty minutes. Before the operation the patient was passing water every fifteen minutes to half an hour, and there was considerable cystitis with ammoniacal urine. On the day following the operation he was able to hold his urine for five hours. The special point of interest in connection with the operation was that he used only small instruments, nothing larger than No. 28 French, although the urethra was roomy. The stone weighed three hundred grains.

THE CONNECTICUT MEDICAL SOCIETY.

Ninety-third Annual Convention, held at New Haven, May 28 and 29, 1884.

The President, Dr. E. B. NYE, of Middletown, in the chair.

[The organization of the Connecticut Medical Society is of a twofold character. It is composed of the members of the county societies, and holds an annual convention, alternately at New Haven and at Hartford. The superintendence and management of the Society are vested in a body known as "The President and Fellows of the Connecticut Medical Society," which

consists of the President, Vice-President, Treasurer, Secretary, and Committee on Matters of Professional Interest of the State Society; of thirty-eight Fellows elected by the county societies; and of the presidents of the county societies, who are *ex officio* vice-presidents of the State society. This body holds an annual meeting on the day preceding the annual convention of the society. All members of the Society have the privilege of attending the meetings of the President and Fellows, and of performing all the duties of Fellows except voting.]

First Day.—Meeting of the President and Fellows.

In accordance with this arrangement, the President and Fellows assembled in the chamber of the Common Council in the City Hall of New Haven, shortly after 3 P. M., May 28th. Among the Fellows present were Dr. E. B. Nye, of Middletown, President; Dr. S. B. St. John, of Hartford, Secretary; Dr. A. T. Douglass, of New London; Dr. J. F. Calef, of Cromwell; Dr. C. J. Fox, of Willimantic; Dr. F. E. Beckwith, of New Haven; Dr. G. C. H. Gilbert, of Westbrook; Dr. C. F. Sumner, of Bolton; Dr. M. Storrs, of Hartford; Dr. George Clary, of New Britain; Dr. H. G. Howe, of Hartford; Dr. W. W. Foster, of Putnam; Dr. R. S. Goodwin, of Thomaston; Dr. T. G. Wright, of Plainville; Dr. W. H. Mather, of Suffield; Dr. F. N. Braman, of New London; Dr. Seth Hill, of Stepany Depot; Dr. P. Cassidy, of Norwich; Dr. J. La Pierre, of Greenville; Dr. E. C. Kinney, of Norwich; Dr. W. C. Wile, of Sandy Hook; Dr. J. Olmsted, of Middletown; Dr. G. A. Shelton, of Huntington; Dr. C. A. Sears, of Portland, for Dr. D. A. Cleveland; Dr. Lewis Barnes, of Oxford; Dr. F. D. Edgerton, of Middletown; Dr. Henry Fleischner, of New Haven; Dr. C. W. Chamberlain, of Hartford; Dr. W. S. Todd, of Ridgefield; Dr. N. E. Wordin, of Bridgeport; Dr. Robert Lander, of Bridgeport; and Dr. W. S. Munger, of Watertown.

THE PRESIDENT'S ADDRESS.—While the committee appointed for the purpose, consisting of Dr. A. T. Douglass and Dr. S. B. St. John, were examining the credentials of the Fellows, the President delivered the annual address. He referred to several matters of interest which had been brought before the Society at the last meeting. One related to the legal status of the Society, and suggested the inquiry whether the charter of the Medical Society had not been annulled by a section of an act relating to the Medical Department of Yale College passed in 1879. He recommended that the Society should take such action as might be necessary to secure an act of the Legislature which should settle the question. He also approved of the proposed additions to the by-laws, which provided that all discussions should be committed to writing; that no voluntary papers should be published which had not been previously read before a county society; and that each county society should select one Fellow and an alternate to serve upon the nominating committee. He had no additional recommendations to make, but invited the attention of the Fellows to the subject of Hygiene, and spoke of the great progress which had been made in preventive medicine, and of the duty of the profession to prevent disease as well as to cure it. He urged the necessity for a code of ethics to secure that courtesy which was desirable in all human intercourse, and especially in the medical brotherhood; and favored an enlightened course in all the affairs of the Society, and a high standard of professional conduct. Both conscience and judgment caused him to indorse a code of ethics. He also mentioned the loss by death of several members of the society, among whom was a former President.

APPOINTMENT OF COMMITTEES.—The Committee on Credentials then made their report, and this was followed by the announcement of the following committees: *On Unfinished Business:* C. J. Fox, F. E. Beckwith, J. F. Calef. *On County*

Resolves: M. STORRS, L. B. ALMY, F. N. BRAMAN. *On Business:* S. B. ST. JOHN, H. G. HOWE, R. S. GOODWIN. *On Honorary Members:* W. H. MATHER, J. LA PIERRE, G. CLARY. *Auditing Committee:* W. W. FOSTER, J. OLMSTEAD. *To Nominate Essayists:* W. C. WILE, F. S. CROSSFIELD.

A CONFERENCE WITH YALE COLLEGE.—Dr. C. A. LINDSLEY announced that the Corporation of Yale College had appointed a committee to confer with a committee of the Connecticut Medical Society in regard to the Yale Medical College. A motion that a committee to represent the Society in such a conference having been passed, Dr. F. L. DICKINSON, Dr. M. C. WHITE, and Dr. O. BROWN were appointed members of the committee.

THE LEGAL STATUS OF THE SOCIETY.—Dr. W. H. CARMALT, in behalf of the committee appointed last year to take into consideration the legal status of the Society, reported that the committee had employed Mr. Chamberlain, of Hartford, to prepare a brief containing all acts of the Legislature relating to the Society, and that this had been submitted to Mr. Simeon E. Baldwin, of New Haven, for an opinion. Mr. Baldwin had stated that, in his opinion, section 6 of the act to incorporate the Medical Department of Yale College, approved March 5, 1879, did not in any way affect the corporate existence of the Connecticut Medical Society.

THE NOMINATING COMMITTEE.—At 3.45 P. M. the Society adjourned for ten minutes, to enable the Fellows from each county to select a member of the nominating committee. On coming to order again, at 4 P. M., the following-named gentlemen were announced as members of this committee: SETH HILL, C. J. FOX, W. R. BARTLETT, L. J. KETCHUM, L. B. ALMY, M. STORRS, F. D. EDGERTON, C. F. SUMNER.

AMENDMENTS TO THE BY-LAWS.—The Committee on Unfinished Business then made their report. Action upon their recommendations was taken as follows: An amendment to the by-laws was made to the effect that all remarks made in the discussion of any scientific question might be committed to writing by the person making them. The proposition that no voluntary paper should be published which had not been read before some county society, and recommended by the latter, was laid upon the table. The amendment that each county society should appoint one of the Fellows elected to serve as a member of the nominating committee, and another as his alternate, to act in his absence only, was passed. Amendments were also adopted to the effect that the Secretary should be a permanent officer; and that he should be paid fifty dollars and the Treasurer twenty-five dollars *per annum* from this year on.

THE CONFERENCE WITH YALE COLLEGE.—The committee which had been appointed to confer with the committee of the Corporation of Yale College next made their report. In behalf of the committee, Dr. M. C. White stated that on April 18, 1884, the Corporation had appointed Mr. Mason Young and Mr. F. J. Kingsbury to inquire into the condition of the Medical Department, and that on May 16, 1884, they had been instructed to endeavor to come to some agreement with the Society whereby the relations heretofore existing between the Society and the College might be dissolved. The committee therefore recommended that the following resolution be adopted:

Resolved, That the President and Fellows of the Connecticut Medical Society desire to cancel and annul the articles of agreement between them and the President and Fellows of Yale College, set forth in the act of the Legislature of the State of Connecticut, entitled 'an act in addition to and alteration of an act entitled an act to incorporate the Medical Society, passed at the October session of 1810,' and any subsequent modification thereof; and hereby authorize the President, Secretary, and Treasurer of the Connecticut Medical Society to execute all such papers as may be requisite to obtain that end, it being under-

stood that such separation shall be without prejudice to any vested interest, contract, or endowment of the College; and that any prerogative heretofore possessed by the Connecticut Medical Society shall revert to the same."

Mr. KINGSBURY, of Waterbury, a member of the Corporation, having been invited to speak upon the resolution, said that the plan of instruction at the Medical School had recently been enlarged. This had entailed additional expense, and, as the number of students had not increased in the same proportion, the deficiency had been made up from the college funds. This was found burdensome. It was possible that it might be found necessary to suspend the school. The old union between the Society and the school had ceased to be useful, and a dissolution of the relation seemed desirable. The faculty of the school believed that they were doing good work, but they had few students. He asked the gentlemen of the Society to inform themselves as to what was being done in the school, and as to whether they could not recommend the school to the young men of their acquaintance who were students of medicine. If they would do this, they would contribute much to the solution of the problem of the future of the school, and at the same time do a good thing for the profession.

The resolution offered by Dr. White was then adopted.

THE SOCIETY'S CHARTER.—A resolution that a committee of one from each county be appointed to consider the revision of the charter of the Society, and that this committee report at a special meeting of the Society to be held before the next meeting of the Legislature, was then adopted. Subsequently Dr. F. L. DICKINSON, Dr. C. W. CHAMBERLAIN, Dr. M. C. WHITE, Dr. G. L. PORTER, Dr. C. J. FOX, Dr. R. S. GOODWIN, Dr. F. N. BRAMAN, and Dr. F. D. EDGERTON, were appointed the committee.

AN ADVISORY COMMITTEE.—A resolution was next adopted that the ex-Presidents of the Society be formed into an Advisory Committee, who should be *ex-officio* Fellows of the Society, their duties to be hereafter specified.

THE FORMER SECRETARY.—Dr. WILE presented a report of the committee which was appointed last year to draft resolutions expressing the Society's appreciation of the labors of Dr. C. W. CHAMBERLAIN, for seven years Secretary of the Society. The report was accepted.

THE PLACE OF MEETING.—An amendment to the by-laws was proposed to the effect that the Society should meet in rotation at New Haven, Hartford, and Bridgeport. This proposal was rejected, as well as another, that the meetings should be held in Hartford every year.

OFFICERS FOR THE ENSUING YEAR.—The nominating committee presented the following list of officers, for whom the Secretary was instructed to cast the ballot of the Society: *President*, B. N. COMINGS, of New Britain; *Vice-President*, E. O. KINNEY, of Norwich; *Treasurer*, E. P. SWASEY, of New Britain; *Secretary*, S. B. ST. JOHN, of Hartford; *Committee on Matters of Professional Interest in the State*, N. E. WORDEN, J. H. GRANNIS, E. A. HILL; *Committee on Examination of Students*, F. D. EDGERTON, H. W. BUELL, LEWIS BARNES; *Committee to Nominate Professors in the Yale Medical School*, C. W. CHAMBERLAIN, G. L. PORTER; *Committee to Nominate a Physician to the Retreat for the Insane*, R. S. GOODWIN, L. HOLBROOK; *Committee on Publication*, I. W. LYON, with the Secretary and the Treasurer, *ex-officio*; *Committee on the Anniversary*, M. STORRS, W. M. HUDSON, J. CAMPBELL; *Dissertator*, W. H. HOLMES; *Alternate*, F. E. BECKWITH; *Delegates to the American Medical Association*, T. M. HILLS, L. S. PADDOCK, W. H. MATHER, C. A. LINDSLEY, W. H. ANDREWS, J. W. BIDWELL, R. BAKER, C. F. SUMNER, II. G. HOWE; *Delegates to the Maine Medical Association*, W. W. FOSTER, W. H. HOLMES; *Delegates to the New Hampshire Medical Society*, F. S. CROSS-

FIELD, G. CLARY; *Delegates to the Vermont Medical Society*, L. B. ALMY, A. T. DOUGLASS; *Delegates to the Massachusetts Medical Society*, C. M. CARLETON, B. W. MUNSON.

THE "PROCEEDINGS" PRIOR TO 1830.—The Society voted to print one thousand copies of the "Proceedings" from 1792 to 1830, with such papers as had been preserved, and to send one copy to each member. The estimated expense of this publication was three hundred dollars, most of which had already been secured by special subscription.

HONORARY MEMBERS.—The Committee on Honorary Members proposed the names of WILLIAM F. HUTCHINSON, of Providence, R. I., and MORRIS H. HENRY, of New York. JAMES E. REEVES, of Wheeling, W. Va., and THOMAS A. EMMET, of New York, who were proposed last year, were elected.

A COUNTY SOCIETY SUSTAINED.—The action of the New Haven County Society in expelling a member who was charged with procuring an abortion was approved.

THE VOLUME OF "TRANSACTIONS."—A vote was passed that seven hundred copies of the "Transactions" of this year be published.

THE REPORT OF THE TREASURER was read and approved by the Auditing Committee.

THE REPORTS OF THE COMMITTEES ON EXAMINATIONS AND ON APPOINTMENT OF PROFESSORS were referred to the Secretary.

The meeting of the President and Fellows adjourned at 6.25 P. M., to meet in Hartford next year.

Second Day.—Annual Convention of the Society.

The members of the Connecticut Medical Society assembled in their annual convention at 9 A. M., Wednesday, May 28th.

THE SECRETARY'S REPORT.—The Secretary, Dr. S. B. Str. JOHN, reported that during the year forty-three new members had joined the Society. Four members had died, five had removed from the State, and one had been expelled, leaving a total membership of 481, an increase of twenty-one over the number reported last year. Two distinguished honorary members had also died, Dr. J. Marion Sims and Dr. Willard Parker.

THE ANNUAL ADDRESS.—The President then delivered the annual address. His subject was "The Medical Profession and its Claims to the Respect and Gratitude of the Community." He referred to the differences between the medical and other professions. The nature of a physician's labor was depressing to body and mind. His rest was always uncertain. His studies covered a broad field, and rendered a lengthy preparation necessary. The sacrifices demanded and unhesitatingly made by the profession in epidemics were most praiseworthy. In recent years the profession had done a great work in the establishment of institutions for the training of imbeciles, and in the treatment of the insane poor more enlightened views had been brought forward. Restraint and confinement in poor-houses had been exchanged for skillful attendance and residence in elegant special institutions. The history of forensic medicine gave numerous instances where medical investigations had been of invaluable aid in detecting crime. Statistics proved that the continued observation and study of disease were leading to a diminished death rate. In comparatively recent times most striking discoveries had been made. Jenner's discovery that vaccination protected against variola; the observation that the inhalation of chloroform or sulphuric ether abolished the sensation of pain, and their use not only as palliative but also as curative agents; and the development of the antiseptic system of treating wounds—each and all of these had saved innumerable lives. The study of the germ theory also had aided in rendering life more secure. The members of our profession were always active supporters of education, they were ever ready to initiate and promote reforms, they were friendly to law and order, and were not hostile to re-

ligion. We should use every endeavor to elevate the standard of medical study. While Latin might not be necessary, it was certainly very helpful. A knowledge of chemistry was indispensable, and that of botany desirable. We were often charged with professional bigotry, but we had no reason to feel discouraged when we realized that never had the broad field of medical science been more diligently and successfully studied than now.

ESSAYISTS.—Dr. WILE, chairman of the Committee to Nominate Essayists, reported the following names: Hartford County, C. W. CHAMBERLAIN; New Haven County, F. H. WHITEMORE; Fairfield County, J. J. BERRY; New London County, A. T. DOUGLASS; Windham County, C. J. FOX; Litchfield County, O. BROWN; Middlesex County, G. W. BURKE; Tolland County, A. R. GOODRICH. The report was accepted.

THE COMMITTEE ON MATTERS OF PROFESSIONAL INTEREST recommended, through their chairman, Dr. W. C. WILE, that the reports which had been sent to them be published in the "Transactions." Accepted.

DELEGATES FROM OTHER STATE SOCIETIES were introduced and made short addresses. They were Dr. ENGLISH, of New Jersey; Dr. BURDETTE and Dr. RICHARDSON, of Massachusetts; Dr. HUNTINGTON, of Vermont; Dr. HAMMOND, of New Hampshire; and Dr. SCHWARTZ and Dr. SMITH, of Rhode Island. Dr. Wile presented to the Society the regrets of Dr. Hutchinson, of Rhode Island, who had been present at the meeting of the day before, but had been obliged to return to Providence in the evening.

MEDICINE FIFTY YEARS AGO.—Dr. R. W. MATTHEWSON, of Durham, read a paper on this subject. He spoke of the change in the *personnel* of the profession which fifty years had made, enumerated a number of remedies and procedures which had come into general use during that time, and some which had fallen into disuse, and eulogized the famous New Haven Medical teachers, Nathan Smith, William Tully, and Benjamin Silliman.

POINTS ON STRANGULATED HERNIA was the title of a paper by Dr. G. W. HARRIS, of Old Lyme. He gave the histories of several cases in which he had operated. He emphasized the necessity for prompt action, and the impossibility of distinguishing the different layers of fascia which composed the covering. He also mentioned the facts that peritonitis might follow taxis or operation, and yet not be due to either, and that a purulent condition increased the danger from operation. He had never seen a radical cure follow an operation for the relief of strangulation. Six cases of death from strangulated hernia had occurred in his immediate neighborhood in which there had been no effort to give relief by operation.

STONE IN THE BLADDER.—Dr. W. H. CARMALT, of New Haven, reported the case of a man forty-two years old. Lithotomy was performed, the patient being under ether forty-five minutes, and ninety-seven grains of calculous material were removed. The man had no untoward symptoms of any sort after the operation, and went home in four days.

AN UNSUCCESSFUL CASE OF WIRING A SIMPLE FRACTURE OF THE PATELLA was also reported by Dr. CARMALT. A man, thirty-eight years old, had been treated a year and a half ago for a fracture of the same patella. Ligamentous union resulted, the fragments remaining an inch and a half apart. A few days before his admission to the hospital he had caught his heel in such a way as to bring all his weight upon the weak knee, and the ligament gave way. Great difficulty was found in bringing the fragments together, even after division of the tendon. The wire broke through, and a part of the patella became necrotic. Thorough antiseptics was observed, and, although there was great reaction, with much inflammation about the patella and the bursa patella, there was no supuration of the joint.

SUBTROCHANTERIO OSTEOTOMY.—Dr. CARMALT next presented a girl, about seven years old, on whom he had performed this operation. The patient had had hip-joint disease and had been cured with the thigh at a right angle with the body. Subtaneous division of the neck of the femur was first attempted, but it was found to be impossible to effect complete division, on account of the effusion around the bone. After an interval, the bone was divided with a chisel between the two trochanters and a wedge-shaped piece was removed. The leg was drawn down and the child enveloped in a plaster dressing from the axillæ to the ankles. The temperature at no time rose more than half a degree, hence the dressings were not removed for a month. At that time there was found to be an inch and a quarter of shortening, instead of the ten inches which existed before the operation.

EXTIRPATION OF THE TONGUE FOR CANCEROUS DISEASE.—Dr. CARMALT finally introduced a man, forty years old, who had been the subject of the operation. The entire fore part of the tongue had been removed, and only a linear scar remained. The operation was rendered almost entirely bloodless by ligation of the lingual arteries. The two great causes of death after operations of this character—septic and pyæmic influences—were avoided by the performance of tracheotomy, plugging of the natural air-passages with borated cotton, and frequent rinsing of the mouth with a solution of permanganate of potassium, until the surfaces granulated, when the plugs were removed. The patient could now talk as well as ever.

AN ULCERATING MUCOUS PATCH OF THE VULVA, WITH CONDYLOMATA ABOUT THE ANUS, was illustrated in a colored drawing, shown by Dr. F. E. BECKWITH, which had been made by Dr. LEIGHTON. These manifestations had disappeared in three weeks under the use of oleate of mercury by inunction, and corrosive chloride of mercury internally, in doses of one twentieth of a grain.

THE SIMS MEMORIAL FUND.—Dr. BECKWITH also read a letter from Dr. Fordyce Barker relating to the fund, and offered to receive subscriptions from the gentlemen who were present.

THE GERM THEORY OF DISEASE.—Dr. N. E. WORDIN, of Bridgeport, read an elaborate, exhaustive, and scholarly dissertation on this subject, which was listened to with unusual interest. His conclusion was that this was the most rational of all theories, and promised the best results.

THE TREATMENT OF CONJUNCTIVITIS.—Dr. F. M. WILSON, of Bridgeport, read a paper based upon ninety-six cases in his practice. He had not treated them with the idea of testing any particular plan of treatment, but had drifted into the way of treating all cases on the two great principles of cleanliness and antisepsis. He had the eye cleansed frequently—once an hour if necessary—with hot oftener than with cold water; and then, which he considered of secondary importance, applied a solution of boric acid.

THE EARLY DIAGNOSIS AND TREATMENT OF POTTS'S DISEASE.—Dr. GEORGE B. PACKARD, of Hartford, read a paper with this title. An early diagnosis seemed to be rare, if one could base an opinion upon the fact that most patients who applied at orthopædic hospitals suffering from this disease were already the subjects of angular curvature; and yet the diagnosis was not difficult if care was taken in the examination. The treatment included tonics and fixation of the spine so as to allow of rest in the open air. Fixation might be secured by plaster of Paris or a steel support. The former was preferable if the disease affected the lower dorsal or the lumbar region of the spine; the latter if it involved the middle or upper dorsal or the cervical region.

MALARIAL DISEASES CURED WITHOUT QUININE.—Dr. AMBROSE BEARDSLEY, of Birmingham, read a paper in which he

expressed no sympathy with the present fashion of loading all malarial patients with quinine. He used instead small doses of aloes, calomel, gelsemium, arsenious acid, gentian, serpentaria, anise, caraway, fennel, salicin, and rhubarb. With these simple remedies he cured the most dangerous and obstinate cases, even where quinine in large doses had failed to affect the symptoms.

Other papers were read by title and referred to the Committee on Publication.

The Society adjourned at 12.50 p. m.

THE ANNUAL DINNER was served at the Athenæum. Dr. J. P. C. FOSTER, chairman of the Anniversary Committee, presided, assisted by Dr. S. H. CHAPMAN and Dr. C. P. LINDSLEY. About seventy physicians were present. Speeches were made by Mayor LEWIS, President PORTER, Mr. CLARENCE DEMING, of the "Morning News," Professor BREWER, Mr. GEORGE A. BUTLER, Dr. ENGLISH, of New Jersey, and Dr. D. BRYSON DELAVAN, of New York.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Meeting of May 26, 1884.

The Vice-President, Dr. ANDREW H. SMITH, in the chair.

THE TREATMENT OF ANKLE-JOINT DISEASE, AND THE MECHANISM OF ITS CURE.—Dr. MILTON JOSIAH ROBERTS read a paper on this subject.

It was not his intention to touch upon the pathology, symptomatology, or diagnosis, but to direct attention to the therapeutic utilization of the vital forces in the treatment. He briefly pointed out the conditions upon which the health of the joint depended, and more particularly the active agencies in producing disease. Coming to the consideration of the principles involved in the treatment, the object was, so far as possible, to imitate the natural conditions by artificial means. There should be limited movement under the restrictions of elastic support. Absolute rigidity should never be sought. The apparatus which he employed was presented. By it the weight was taken off of the affected joint to the extent desired, motion was allowed, the patient was able at once to go about, and the apparatus could be applied and removed in a few minutes. A patient was presented who had suffered from a severe form of synovitis and caries of the ankle joint, not having been able to stand and walk for two or three months. Several spicules of dead bone had been discharged through fistulæ leading down to the joint. An apparatus was applied which enabled the patient to walk the same day. An elastic cap aided in getting rid of the discharges. The patient was cured, having a perfect joint, within eight months. The author referred to his paper read at the last meeting of the Medical Society of the State of New York for a fuller explanation of the principles involved in the treatment.

Dr. F. LANGE believed that some cases would be found in which the treatment advocated by Dr. Roberts would not be applicable, and we should find it necessary to resort to the operation of excision. It was important to know exactly what structures had been involved in cases in which a cure resulted with motion. He would not be understood as saying that he would perform excision in every case of ankle-joint disease.

Dr. J. L. CORNING could testify to the extent to which the diseased process had gone in the case reported by Dr. Roberts, and said the results of treatment and the rapidity with which they took place were marvellous.

Dr. J. F. RIDLON described the apparatus used in the Orthopædic Dispensary, and, referring to that presented by Dr. Roberts, said he thought the impression should not be allowed to go forth that it was adapted to all cases. Some patients even recovered without any apparatus.

Dr. G. R. ELLIOTT spoke of the duration of the treatment

under the method brought forward by Dr. Roberts as being much shorter than with methods intended to produce ankylosis.

Dr. H. LEVY thought the rule that rest should be observed in the treatment of diseased structures was not as strictly observed by Dr. Roberts as it should be.

Dr. ROBERTS, in closing the discussion, said he did not wish it understood that he professed to have a cure-all for every case of ankle-joint disease. Regarding Dr. Kidlon's criticism on the strength and effectiveness of the apparatus, it was not necessary to have a support of such strength as was required when the rigid apparatus was worn.

Dr. W. M. CARPENTER moved that when the society adjourn it adjourn to meet on the fourth Monday in September. Carried unanimously.

OVERCROWDING IN SCHOOLS.—On motion, the report of the Committee on Hygiene on the overcrowding of the public schools was not read, but ordered to be printed in the minutes.

PASSENGER SHIP MEDICAL SERVICE.—Dr. J. A. IRWIN offered resolutions urging Congress to take action regarding the sanitary conditions of ocean steamships. Seconded by Dr. C. C. Lee, and carried unanimously.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

Meeting of April 9, 1884.

MALIGNANT PUSTULE.—Dr. W. S. JANNEY read a paper founded on four cases that had come under his observation in the course of thirty years' practice.

The synonyms of malignant pustule, as given by various authors, were: Contagious carbuncle, malignant carbuncle, anthrax, and charbon, other names being used to designate the more diffused and general forms of the disease. It was defined to be a specific contagious disease, communicated to man from disease of horned cattle, horses, sheep, and other herbivora, known as splenic fever, and due to the presence in the system of the *Bacillus anthracis* of Cohn, or bacteridium of Davaine. The local or external form of the affection, malignant pustule proper, was a carbunculous swelling having specific characters, attended with more or less intense surrounding inflammatory edema; constitutional symptoms might be slight or severe, and the disease was often fatal. The symptoms and course of malignant pustule varied greatly with the form of the disease. Authors described at least three distinct forms: 1. Malignant pustule or carbuncle proper, the form from which the names of charbon and anthrax were derived; usually it occurred as a primary lesion due to direct inoculation; the seat was either on the face, neck, hands, or arms, those parts most exposed to inoculation. 2. Malignant anthrax edema, without definite pustule, corresponded in the main with malignant pustule proper. The eyelids were the parts most frequently affected, but it might occur elsewhere. 3. Internal anthrax: this differed greatly from the external, and might be general, having no special lesion or accompanied by local affection, usually pulmonary or gastro-intestinal.

[Dr. Janney then read the histories of four cases of malignant pustule proper.]

From the observation of these cases it appeared that the disease might be divided into four periods or stages—first, the period of incubation, which might be from a few hours to fourteen days, with no prodromes; second period, the formation of pimple, papule, and pustule, lasting from twelve to twenty-four hours; third stage, the extension of the edema and inflammation, occurring twelve hours after the formation of the pustule; fourth, the stage of gangrene, occurring from twelve to twenty-four hours later, the disease extended by the poison being

carried by the superficial lymphatics only. He was led to this conclusion from the fact that in three of the cases the disease extended from the right side of the pustule, curving upward over the face; and not until the lines of inflammation or edema had reached above the line of Wharton's duct did the lips show evidence of disease. Again, the disease in all the cases was confined to one side of the face, head, neck, and scalp, and did not pass over the median line of the face or the median line of the neck posteriorly.

The immediate cause of death in three of the cases was, he believed, thrombus of the cerebral veins or sinuses. The patients rapidly became comatose, and had stertorous breathing and complete paralysis before death, all symptoms of compression of the brain. Billroth had reported a case of death from malignant pustule in which the post-mortem examination showed thrombus of the temporal veins that was traced to the ophthalmic, and through the ophthalmic to the brain. Bartholow gave as the most frequent cause of sudden death in erysipelas of the face and head, thrombus of either the longitudinal, the cavernous, or the lateral sinus.

The *Bacillus anthracis* was a bacterium, first discovered by Pollender in 1849. All parts of the bodies of animals dead of the disease were actively poisonous, and might convey it by direct or mediate contagion; it might arise from eating the flesh, though the poison was said to be destroyed by cooking; contagion might also be conveyed by butter or milk. The bites of flies might also convey the poison. Contagion occurred in those who had to deal with the wool or hair of animals which had died of the disease, such as wool packers and sorters, horse-hair cleaners, furriers, and tanners. The poison might enter the system either by local inoculation or by inhalation of the dust containing it. The diffusion of the poison by water, and its distribution by means of wool-waste and bone-dust, used as manure, especially deserved notice as capable of spreading the contagion.

Dr. TYSON regretted that he could add nothing from personal experience in this interesting disease. It was to be regretted that there was no microscopic study of the blood, with a view to determining the presence of the *Bacillus anthracis*, for, although there appeared to be less doubt as to the causative relation of the bacillus of this disease than of any other, it was still important that observations should be multiplied in this country, most of the investigations having been made abroad—in France and Germany.

Dr. SHAKESPEARE thought it would have been very interesting to note the microscopical appearance in these cases, and to have proved the diagnosis by inoculation. The author of the paper admitted the *Bacillus anthracis* as a cause, or at least as a concomitant of the disease. He could not agree with him as to the inference from failure to inoculate the lower animals. It was known that these might resist infection, either from protection by previous attacks or from special idiosyncrasies. But such protection could scarcely be said to exist when the disease did not exist, and anthracosis was extremely rare among the cattle of this country. By inoculation in some animals, such as the house-mouse, we could nearly always make a diagnosis in the earlier stages, and, if resort were had to the microscope, the diagnosis was nearly certain. He had paid considerable attention to the subject of anthrax in the lower animals during a recent visit to Koch's laboratory. It was worthy of remark that the field-mouse, although much like the house-mouse, and some species of sheep, seemed to resist the infection. We were principally indebted to French observers for our knowledge on this matter. He had had no difficulty in isolating, cultivating, and inoculating the anthrax bacillus. The animals died promptly, and their blood-vessels were found ob-

structed, and in the lungs absolutely plugged by the typical bacilli, arranged in twisted filaments. The cases in the human subject were rare in this country, and it was remarkable that four should have occurred in the practice of one surgeon in so short a time. The occurrence of this and other disease in man, as an infection from animals, showed the great importance of scientific study of the diseases of these animals, a matter which in this country had not yet received adequate consideration.

Dr. W. H. PANCOAST said that he had been present some years ago at a meeting of the Academy of Medicine in Paris during a heated discussion of this subject. Pasteur, he believed, was present, and took part in the debate. It was in print that Pasteur stated that the bacillus might be developed in the earth surrounding buried carcasses, and be thus disseminated—that the worms in the earth might work to the surface and distribute the bacillus to the adjacent vegetation. If this was a fact, it might explain the origin of the cases described by Dr. Janney occurring among farmers. He had never seen a case of malignant pustule in his own practice; but several years ago he saw one in the service of his father, in the Pennsylvania Hospital. The patient was a knacker from "the neck," and had acquired the contagion in skinning some dead cattle. The pustule was upon the right arm, if he recollected correctly. In spite of every effort, the patient died from the poison. He was impressed with the value of the hot iron in such cases—making free incisions, and pushing the iron at a white heat into them and into the wound, so as to destroy the bacillus. The hot iron not only destroyed the part it touched, but the heat radiated beyond and effected molecular change in the deeper parts. Carbolic acid did not penetrate so deeply. He thought it important to open the pustule freely, and to tap with a fine-bladed knife the surrounding swollen and inflamed tissue; to use what he called the antiphlogistic touch of the knife—not simple or multiple incisions, but numerous punctures, as many as were required to relieve the inflammation or let out the stagnant blood. He found this method very useful in many chronic and acute inflammatory congestions. In opening an ordinary carbuncle, one that was non-malignant, he also thinks it important to incise freely. In an ordinary boil there were only a few masses of cellular tissue inflamed, and a simple straight incision from without inward, and out again, would free them all; but in a carbuncle there were so many packets of inflamed cellular tissue that a simple linear incision and even a crucial one would not answer. He therefore made one free incision through the inflamed mass, and then, with the same curved bistoury, incised freely, and in every direction subcutaneously, the sides of the inflamed mass on each side of the straight incision. By this method, with only one incision, he opened freely and reached all the inflamed tissues, making the greatest antiphlogistic impression, and yet leaving only one straight scar.

Dr. S. ASHURST recalled the case referred to by Dr. Pancoast as occurring in the practice of his father, Dr. Joseph Pancoast. He used, however, a more energetic means than the hot iron, viz., a strong solution of zinc chloride. For his part, he did not like the hot iron.

Dr. PANCOAST asked if inoculation of the lower animals would show results sufficiently early to be of use in diagnosis.

Dr. SHAKESPEARE replied that small animals—such as mice—died in twenty-four hours after inoculation.

Dr. TYSON asked if the appearance of the pustule was an evidence of the general involvement of the system, and, if so, what advantage was to be gained by treatment of the local manifestation by cauterization or excision.

Dr. SHAKESPEARE said it was true that, after the disease had reached the general system, cauterization of the local manifestation, except in so far as the latter constituted a depot for the

continued production of the disease germs which might still be added to those already in the system at large, was useless.

Dr. JANNEY thought that many cases of malignant pustule occurred in this city, and were not reported. He could not be absolutely positive that his cases were malignant pustule, because no microscopic examination was made. He judged from the character and the clinical history. In three of the cases no cause could be traced; in the fourth there was only the supposition of cause, since the patient had been among conditions that might be a source of infection. Dr. Welsh saw one of the cases, and thought it was malignant pustule; Dr. D. Hayes Agnew saw the fourth, and pronounced it that disease. As regarded treatment, in one of the cases it was evident that no local treatment would avail. He had a theory that in the favorable case the early incision and the injection of carbolic acid into the lips destroyed the bacillus germs, which had as yet not extended to the cheek. The remedy that seemed of greatest value in this disease, as indeed in other forms of blood-poisoning, was chlorine-water.

Dr. PANCOAST stated that he liked chloride of zinc as an alterative application, having learned its value from his father's practice; that he used it on chancres, cutting them out when possible, and applying it on the raw surface, and also upon morbid growths. But in the bites of dogs he also used the hot iron for its radiating effect; and, while he might use it as an application to malignant pustule, yet he would also use the hot iron, pushing it into the incision.

Dr. SHAKESPEARE regarded the affection more commonly called anthrax as a very different thing from malignant pustule. It was the latter which had the same cause as anthrax in the lower animals. The remarks of Dr. Pancoast concerning carbuncle recalled his intention to say that the incandescent iron was a more proper remedy for malignant pustule. It was our most effective bactericide. Carbolic acid might not penetrate nor destroy even when we used the concentrated solution, for this became diluted by contact with the tissues. The bacillus of anthrax often contained spores; these would be propagated from pus and could not be killed by dilute carbolic acid. It appeared that the most efficient chemical agent for the purpose was a strong solution (1 to 400) of corrosive sublimate. But, since it was a question of life or death of the patient, with the probabilities against him, he thought the surgeon should not be influenced by cosmetic considerations, but should promptly and with a free hand apply the most certain means of killing the bacillus while it was brooding, and before it had spread beyond the pustule.

HENRY LEFFMANN, M. D., *Reporting Secretary.*

PATHOLOGICAL SOCIETY OF PHILADELPHIA.

Meeting of May 33, 1884.

The President, Dr. TYSON, in the chair.

PAGET'S DISEASE OF THE NIPPLE.—Dr. W. G. MACCONNELL, in behalf of Dr. JOSEPH HEARN, presented a case that had been removed by Dr. Hearn at the clinic of the Jefferson Medical College on the preceding Saturday. The patient, who was thirty-nine years old, had been married nineteen years, and had four children and one miscarriage. No other member of her family had been the subject of a tumor. Four years ago, following a pustular eruption on the abdomen, a lump was noticed in the left breast, which was the seat of lancinating pain of an intermittent character. Previous to the discovery of the lump, an eruption of an eczematous nature was noticed for seven or eight months. At the time of the operation the right nipple was thoroughly retracted; indeed, it had entirely melted away. There was no axillary involvement, although a gland

was noticed at the upper and inner quadrant of the breast. On section of the tumor, after its removal, several small nodules of a hard, fibrous consistence were encountered, which, on microscopical examination, were found to be the seat of carcinoma of a scirrhous nature. The gland revealed a similar condition.

COLLOID CARCINOMA OF THE BREAST.—This specimen also had been removed by Dr. HEARN at the Jefferson Medical College clinic. The patient, an unmarried woman, sixty-seven years old, was in good general health, although of a phthisical family. No other member of her family had had any tumor. About three years ago she felt a lancinating pain in the right breast, and, on examining the breast, she found a lump, which was hard, roundish, and about as large as an English walnut. It increased in size continuously, and at the end of a year and a half it had attained the size of an egg. Two months before her admission to the hospital she resorted to a quack, who applied a salve, which, she says, caused some bleeding. She states that the breast began to "gather," and, one week previous to the operation, it broke and a dark-greenish fluid escaped, followed by the extrusion of a mass of greenish-colored slough. The growth was attached to the overlying skin, but not to the pectoral tissues beneath; the subcutaneous veins were enlarged and prominent; there was no glandular involvement. On section, the tumor was found to be densely hard and the seat of small cavities filled with a glairy, gelatinous, semi-solid fluid. Microscopic examination showed alveoli filled with epithelia that had undergone fatty degeneration, not a few of them showing the peculiar laminated appearance of colloid. The connective tissue of the stroma was in a state of active proliferation, due probably to the inflammation resulting from the cystic change already mentioned.

SARCOMA OF THE TESTICLE.—Dr. G. DE SCHWEINITZ showed a specimen that had been removed from a man, thirty-seven years old, a patient of Dr. John Ashhurst's, in the University Hospital. The patient's father and mother were living and in good health; his grandparents had died at an advanced age, having been healthy through their lives. Of two brothers and two sisters, all were living, and three of them had been thus far in good physical condition. One sister had had a growth removed from the orbit, probably a sarcoma, which was now beginning to recur. His own health had been good, and he denied having had any venereal disease. Two years and a half ago he first noticed a globular swelling at the bottom of the left testicle, which gradually increased in size until eight months ago, since which time its growth had been so rapid that at the time of the operation the circumference of the testicle was fourteen inches and a half. The pain had been insignificant until last April, but since then there had been severe dragging pains. The inguinal glands on either side were slightly enlarged. The growth occupied the body of the testis, being surrounded by the tunica albuginea and the tunica vaginalis, which were intact. The specimen was somewhat irregular, moderately soft, blood-stained mass, with an area of cystic degeneration at one end. Microscopic examination showed it to be a sarcoma of the round-cell variety, the cells being moderately large, containing oval nuclei and, some of them, nucleoli. In places a faint reticulation was demonstrable, producing a picture similar to the "lymph-gland-like" round-cell sarcoma.

NEW YORK OBSTETRICAL SOCIETY.

A STATED meeting was held January 15, 1884, W. M. POLK, M. D., President, in the chair.

DERMOID CYST IN THE PELVIC CELLULAR TISSUE.—Dr. T. A. EMMET presented a specimen of dermoid cyst which had been

removed ten days before from a woman about twenty-two years old, who had been in good health until puberty, but since that time had suffered from very severe dysmenorrhœa, which had gradually reduced the general health until she had become a confirmed invalid. There had been repeated attacks of pelvic inflammation. She entered the hospital in the autumn of the past year, and every means were resorted to to relieve her sufferings and restore the health, but without success. All of his colleagues at the Woman's Hospital saw the patient, but were unable to make a diagnosis beyond that of pelvic inflammation. On passing the finger into the posterior vaginal *cul-de-sac*, the impression was received as of a tumor growing from nearly the entire length of the posterior wall of the uterus—possibly a fibro-cyst or a fibroid tumor. The patient had suffered so much, and her mental powers were becoming so greatly affected, that an exploratory abdominal incision was decided upon, with the hope of finding and removing the cause. At the operation Dr. Emmet was surprised, on cutting through the peritoneum, to come upon a dermoid cyst in Douglas's *cul-de-sac*, below and entirely outside of the peritoneum, and without any connection with the ovary or any other organ. He then read the pathologist's report.

Dr. Emmet further remarked that it was impossible to find either ovary, so extensive had been the adhesions excited by repeated attacks of cellulitis. The left Fallopian tube, which seemed to be somewhat enlarged, was removed. He inquired whether the occurrence of a dermoid cyst in the pelvic cellular tissue, outside of the peritoneum, and having no connection whatever with the ovaries, was not unusual. This was the only case of the kind which he was able to recall. The case also illustrated the advantage often of opening the abdomen for diagnostic purposes.

Dr. H. J. GARRIGUES said that without doubt the case was a rare one, but he would call attention to the fact that dermoid cysts were not always developed in connection with the ovaries, but often under the skin, and sometimes even in the internal organs. He was therefore not surprised that one should have been developed in the locality referred to. For the explanation we should probably have to go back to the beginning of fetal life, at which time the foundation of the condition was probably laid. We could easily imagine that at this time some small portion of the epiblast became included in the mesoblast, and, in the course of time, becoming separated from the epiblast, might develop into the form of a dermoid cyst in any portion of the interior of the body.

Dr. W. M. CHAMBERLAIN thought that the late Dr. Peaslee some seven or eight years ago presented a specimen of dermoid cyst, of about the size of that presented by Dr. Emmet, which had developed anteriorly and beneath the peritoneum in the iliac fossa.

UTERINE CASTS.—Dr. GARRIGUES presented a specimen with the following remarks: When fresh it was 6 cm. long, 2½ cm. wide, 1½ cm. thick, and of a pyriform shape. The outer surface was grayish; the cut surface was of a dark-red color; it was soft and stringy, and appeared very much like a fibrinous clot. The odor was offensive. The physician who brought the specimen to him said it was one out of a hundred, meaning by that that many similar ones had been passed. The patient said there came one after each menstruation, but added that it came only in case there had been coition. If, during the whole period between two menstruations, no connection took place, none would come. Menstruation was always somewhat protracted. The present body had come seventeen days after the beginning of a menstrual flow. Dr. Garrigues had examined part of the specimen, and had found that the sections, by removal from one saucer to another, would constantly break. The microscopical

examination showed it to be rather peculiar. It consisted of a net of fibrin filled with small round cells. Consequently it was not a blood-clot. The blood was gone, so to speak; the fibrin had been left, and was full of cells. The question arose, where did the small cells come from? So far as he knew, red-blood corpuscles were never changed into such cells. Might they not have been due to wandering blood corpuscles from the walls of the uterus, or to proliferation of the colorless blood corpuscles originally contained in the clot? It resembled connective-tissue stroma, but the network was composed of fibrin and not of connective tissue. Compared with other specimens which had been presented to the society, it showed the importance of a microscopical examination of bodies passed from the uterus. About three years ago Dr. Skene presented a so-called clot, which, upon microscopical examination, Dr. Garrigues found to be composed of placental tissue. Subsequently he had reported on another body passed from the womb, which proved to be uterine tissue, illustrating dissecting metritis, eight examples of which he had now seen. The specimen now presented might easily be mistaken for the product of conception, on account of the patient's assertion that such bodies were expelled only after coition.

Dr. CLEMENT CLEVELAND had to-day received a specimen, the gross appearance of which resembled very much the one presented by Dr. Garrigues; it looked like uterine tissue. The patient was twenty-seven years of age, and had suffered regularly from intense dysmenorrhœa for years, the pain coming on before the onset of the flow. The clot was passed every month. There was anteversion.

Dr. GARRIGUES thought it probable that the specimen consisted of the membrane thrown off in membranous dysmenorrhœa. There was another form of body cast off from the uterus, known to be due to exfoliative endometritis, three cases of which had been described by Kubasson ("Ztschr. f. Geburtsh. u. Gynäk.," ix, 1883, p. 310). The whole mucous membrane lining the uterus was expelled in the form of a sac. The cast was so complete as even to have taken with it a thin layer of muscular tissue beneath the mucous membrane. It had nothing to do with menstruation.

Dr. CLEVELAND remarked that the specimen to which he referred bore no resemblance to the membrane sometimes discharged by those suffering from dysmenorrhœa.

Dr. A. S. CLARKE was reminded of a case, recently observed, of which he had not seen an example before. The patient, a young woman, married, had had one miscarriage, and complained of very great pelvic and uterine uneasiness. Sharp antelexion was found similar to congenital antelexion. He attempted to effect dilatation by means of a laminaria tent, preparatory to the use of a stem pessary, but the canal was so tightly closed that he was unable to introduce the tent up to the fundus. During the night it was pressed out, and was not replaced. The evening of the next day he was sent for, and, on his arrival, was shown a mass, similar in size and appearance to that presented by Dr. Garrigues, having a very offensive odor. It had been passed from the womb. The central portion was perforated by a canal corresponding to the uterine canal. Dr. Clarke was of the impression at the time that it was composed of inspissated mucus, which the uterus had been excited to discharge by the presence of the tent. The patient was afterward much relieved.

A NEEDLE FORCEPS.—Dr. CLEVELAND presented a forceps with grooves for holding the needle firmly in one of six positions, preventing the possibility of its slipping. In the forceps used at the Woman's Hospital the needle was grasped by a copper surface, and as this became worn the needle was apt to slip.

Dr. T. A. EMMET remarked that Dr. Sims had made use of a forceps similar to the one presented. The objection to its use was that the hard metal broke the needle; hence the substitution of copper. The best needle-holder which he had seen had been invented many years ago by a Dr. Cutter, of Newark, in which the principle of action was like that of a nut-cracker.

Dr. B. F. DAWSON thought the quality of the needles for sale in the American market was more at fault than the needle-holder; they were not properly tempered, and broke or bent easily if firmly grasped. Hence he had been in the habit of obtaining his needles from England, or tempering them himself.

Dr. EMMET said that, in re-tempering a needle, he let it cool in hot oil.

Dr. CHAMBERLAIN believed the needle was less liable to be broken if the handle of the forceps contained a spring, conveying to the hand a sense of the degree of pressure with which the needle was being grasped.

RUPTURE OF AN OVARIAN CYST, THE CONTENTS BECOMING CLOSED IN BY PERITONITIS.—Dr. T. A. EMMET related the following case: In July last a woman with a supposed ovarian tumor was brought to his office from Memphis, having been taken from her bed during an attack of peritonitis, and arriving more dead than alive. She was placed under Dr. Harrison's care, and it was determined, if she recovered sufficiently from the peritonitis, to perform ovariectomy, which was accordingly done in the middle of July. Dr. Emmet found to his surprise, on cutting through the abdominal wall, that he had opened directly into a large space. The fluid, which was dark, not unlike ink in appearance, was emptied out apparently from the abdominal cavity and not from an ovarian sac. As soon as the cavity had been washed out, numerous long and large strips of membrane, apparently composed of the walls of the sac, were readily peeled off. On reaching the portion covering the stomach there appeared to be another cyst, but it proved to be the distended stomach. The case evidently was one of ovarian tumor which had ruptured, and the contents become encysted by the products of inflammation; the walls then rotted, or softened, and could be peeled off in the manner mentioned. He had never seen a similar case. Dr. Harrison would give the result and the history of the after-treatment.

Dr. G. T. HARRISON said that after the operation he continued to irrigate the cavity very freely with an antiseptic fluid, and it sometimes required an hour and a half before the liquid came away clear. This was continued for some weeks. Finally the patient was able to sit up, had a good appetite, and was doing well when symptoms of intestinal obstruction developed. Dr. Lee, and afterward Dr. Weir, were called in consultation. Dr. Weir opened the abdomen, and, as was believed, relieved the constriction. But it proved not to be so. The intestine was then opened and stitched to the abdominal wall. A further exploration was contemplated if necessary the next day, but the patient died in the mean time. At the post-mortem an adhesive band, stretching from one coil of intestine to another, was found to have been the cause of the constriction. Had it been discovered during life, the patient might easily have been relieved.

The PRESIDENT said a very important question was raised by this report, namely, as to just how far we should interfere in searching for an intestinal obstruction. There could be no doubt that when the surgeon searched for any great length of time, feeling around in the abdominal cavity, he jeopardized the patient's life by that procedure alone, and yet, on the other hand, if he did not do so he was liable to have the mishap which occurred in this case. The question had been raised before, but its importance would justify further discussion if any of the members had any suggestions to make.

PAPILLOMATOUS OVARIAN TUMOR AFFECTING THE PERITO-

N.EUM.—Dr. Dawson reported a case as follows: About a year ago Dr. Griswold sent a patient to his office with a view of ascertaining the character of a mass which he had detected in the pelvis. Dr. Dawson made an examination, and found a slightly fluctuating mass occupying the whole left pelvic region, somewhat movable, but not sufficiently so to point distinctly to a free ovarian cyst. The patient complained only of occasional pains and some dysmenorrhœa. That the mass contained fluid seemed very evident to Dr. Dawson, although Dr. Griswold believed differently. He made arrangements to see the patient again within a few weeks, with a view to proving the fluid nature of the tumor. He was then disposed to think it an ovarian cyst, but aspiration was decided upon to make the diagnosis positive. About a pint of cloudy fluid was withdrawn, which, under examination, pointed to an ovarian cyst. The patient was a strong woman, in good health, and was advised to let the tumor alone for the time being, and report further. She returned with Dr. Griswold last autumn, saying that she suffered a great deal of pain. The mass was found to have become considerably larger. It was still rather immovable and not connected with the uterus, and, from the history of the case and the examination of the fluid, he was still of the opinion that it was an ovarian cyst. Dr. Lee saw the patient, and concurred in the diagnosis. The patient was told that, if her condition demanded relief, she might return and an exploratory incision would be made. She returned on the 19th (15th?) of last month, complaining of marked distress. A purely exploratory opening was determined upon. An incision two inches and a half long was made, and it was noticed that at the lower angle of the incision there was a decidedly papillomatous appearance. All the gentlemen present were immediately struck by the papillomatous development of the peritonæum which had been incised. As was expected, an ovarian tumor was found firmly adherent to the intestines and to all surrounding parts, and Dr. Dawson decided not to remove it, but to sew up the abdominal wound and, if necessary, establish drainage by the vagina subsequently. The temperature did not rise above 100° F. at any time; in eight days the patient was sitting up, and on the twelfth was walking about, no unfavorable symptom having developed. As the general health was becoming affected, and the patient showed the peculiar *facies*, a rapid destruction of life was looked for. Very strict cleanliness was observed, the towels and the napkins were carefully washed, the patient was bathed, the operating-room was scrubbed, all under Dr. Dawson's immediate supervision. But, further than strict cleanliness, antiseptics were not employed.

Dr. EMMET remarked that there was generally but little vitality left in these patients, and they often died on the operation-table.

Dr. Dawson thought it would have been better for his patient had his expectations been fulfilled, and she had died from the operation. But, as it was, she made a remarkably good recovery, and that notwithstanding he had been unexpectedly compelled to employ improper sutures in closing the wound.

SUPPOSED ACUTE YELLOW ATROPHY OF THE LIVER WITH PREGNANCY.—Dr. CHAMBERLAIN gave the history of the following case, for the purpose of asking a question regarding diagnosis. He had been called in consultation to see a primipara in the middle of the seventh month of pregnancy, who had been attacked with intense pain across the epigastrium. No cause for indigestion, nor for the agonizing pain located at the epigastrium, had been recognized. It was shortly followed by colliquative diarrhœa to the extent of seven or eight passages. Then there came dark vomiting. These phenomena perhaps occupied the first twelve to fourteen hours. When he first saw her

she was very decidedly pallid, and was very tender across the epigastrium, but not lower down on the abdomen. She was of small frame, and the tension of the abdomen was such that little could be determined by palpation and percussion. He believed the case to be one of icterus malignus, or acute yellow atrophy of the liver—a very rare disease, but which in at least half the recorded cases had occurred in the young parturient woman. The icterus increased, the pain in the epigastrium did not diminish, and could only be controlled by morphine. The diarrhœa ceased, and the patient passed into a typhoidal condition. He had expressed the belief that premature labor would occur. Labor began on the third day, and was completed within about sixteen hours. Having seen but one case of acute yellow atrophy, in which the patient died the second day after delivery, he had but little doubt that such would be the issue in the present case. Although the pains were weak, yet the pelvis was roomy, pregnancy had advanced to only seven months and a half, and delivery was effected by the unaided efforts of nature. As it had been noted that hæmorrhage usually attended such cases, the patient was given a full dose of ergot just before delivery. From the day of delivery the woman improved. At the time of delivery the temperature was 103° F., the tongue was brown, the intellect wandering. She gradually came out of this condition, and was now believed to be convalescent. So far as reliance could be placed upon a physical examination, under the circumstances, the left lobe of the liver was retracted. The question arose whether this was really a case of icterus gravis, or acute yellow atrophy, in which recovery took place. An interesting feature in the case was, that, although delivery had been completed naturally, he was much surprised to hear the next day that there was a certain black swelling upon the vulva. Her family physician, upon examination, found the surface of one labium gangrenous, and this afterward sloughed. From the low and typhoidal condition of the patient, and from the presence of a constantly breaking-down mass of gangrenous tissue in the vulva, he thought they were in a very fair way for all the sequelæ of sepsis, but there were none. The tissues, as fast as they broke down, were detached, and antiseptic irrigation was employed.

Dr. A. JACOBI asked what the condition of the urine was.

Dr. CHAMBERLAIN said there was no tyrosin, leucin, nor albumin. There were a few blood discs. In the case of acute yellow atrophy of the liver already referred to, the vomiting and the diarrhœa did not cease until death.

HENRY J. GARRIGUES, M.D.,

B. F. DAWSON, M.D.,

FRANK P. FOSTER, M.D., *ex officio*,

Committee on Publication.

Miscellany.

THERAPEUTICAL NOTES.—*Tobacco as an Antizymotic.*—There is a popular notion that the use of tobacco is in some degree a protective against the infectious diseases. In the "Montpellier médical," quoted in the "Bulletin général de thérapeutique," Dr. Pecholier supports this belief, saying that he considers tobacco an energetic parasiticide capable of acting upon microzymes and microbes, and that, while he thinks its abuse liable to produce well-marked effects on man, he is nevertheless convinced that it is capable of rendering important service in protecting him against epidemic and contagious diseases. He lays particular stress on the immunity against phthisis acquired by workers in tobacco.

Osmic Acid in the Treatment of Peripheral Neuralgias.—Dr. A. Eulenburg ("Berliner klinische Wochenschrift," 1884, No. 7; "Centralblatt für klinische Medicin," April 19, 1884) gives his experience with the hypodermic use of osmic acid in the treatment of peripheral neuralgias, in which he used a one-per-cent. solution. Twelve cases were treated, the dose being almost always 0.06 grammes. In no instance were any unfavorable effects produced. The duration of the treatment was from one to six weeks, and the number of injections in the individual cases varied from three to fourteen. The cases included trigeminal, occipital, brachial, intercostal, lumbo-sacral, sciatic, and multiple neuralgias, partly recent and partly of long standing. The injections were always given *in loco morbi*—i. e., as near as possible to the affected nerve. The results were not very inspiring—out of twelve cases, only three cures (without relapses within a period of from two to fourteen weeks), with four of greater or lesser improvement and five of total failure. The three cases of cure were rather recent and uncomplicated cases, apparently of neuritic or perineuritic origin. The quantity of osmic acid used in these three cases was between 0.025 and 0.4 grammes. The author thinks it certain that the drug is not wholly inoperative in peripheral neuralgias, but that it is in no sense a specific.

Paraldehyde in the Treatment of Delirium Tremens.—Gugl ("Zeitschrift für Therapie," 1884, No. 4; "Centralblatt für klinische Medicin," 1884, No. 20) speaks highly of the action of this drug in delirium tremens, on the strength of three cases treated with it. In every instance it proved a prompt hypnotic, and in no instance were unpleasant symptoms produced. The dose was usually given with twice or three times the same amount of tincture of orange-peel, with syrup of orange-peel, or in about one eighth of a litre of sweetened water, the whole making a mixture against which the patient's befuddled sensorium did not rebel. The author considers paraldehyde absolutely free from danger, even in doses of six to eight grammes.

THE WATERS OF SULPHUR SPRINGS, TEXAS.—Dr. J. M. Hooper, of Sulphur Springs, Hopkins County, Texas, sends us the following analyses of the water of two wells in that town. There is one well, he remarks, that has not yet been examined, which is thought, however, to be superior to these. He adds that he will be happy to answer any questions about the waters of the various wells in the town.

The water of the Weaver Well is acid in reaction, with a specific gravity of 1.008, and each gallon contains the following solid constituents:

	Grains.
Sulphate of ferric oxide	33.421
Sulphate of aluminium	23.235
Sulphate of magnesium	24.345
Sulphate of lime	45.678
Sulphate of sodium	1.342
Sulphate of potassium	0.849
Chloride of sodium	1.360
Carbonate of lime	4.286
Phosphate of lime	0.633
Silicic acid	1.425
Free sulphuric acid	1.211
Nitrous acid	a trace.
Organic matter	2.473

The Pate Sour Well, also of acid reaction, has a specific gravity of 1.0096, and in each gallon the following solid constituents have been found:

	Grains.
Calcic sulphate	84.713
Ferric sulphate	63.194
Magnesian sulphate	22.991
Sodic chloride	5.017
Silex	1.944
Organic and volatile matter	3.797
Free sulphuric acid	1.321
Iodine	a trace.

AN UNINTENDED TRIBUTE TO VIRCHOW.—Prince Bismarck is reported to have said recently, in a letter declining an honor that had

been proffered him, that nothing under Heaven would tempt him to become in any way a colleague of Virchow's.

PREHISTORIC MAN IN EGYPT AND SYRIA.—At the request of the Council of the Victoria Institute, of London, we publish the following:

"A gala meeting was held by the Victoria Philosophical Institute of London in the second week in May, at which its members gave a worthy welcome to Vice-Chancellor Dawson, C. M. G., of McGill University, Montreal, at whose instance the British Association visits Canada this year. The Society of Arts kindly lent its premises for the occasion, and its great theatre was crowded in every part long before the hour of meeting. The chair was taken by Sir H. Barkly, G. C. M. G., K. C. B., F. R. S., who—after the new members had been announced by Captain F. Petrie, the secretary—welcomed Dr. Dawson amid loud applause, and asked him to deliver his address: It was on 'Prehistoric Man in Egypt and Syria,' and was illustrated by large diagrams, also flint implements and bones collected by Dr. Dawson himself on the spot during his winter tour in the East; Professor Boyd-Dawkins, F. R. S., kindly assisted in the classification of the bones. In dealing with his subject, Dr. Dawson remarked that great interest attaches to any remains which, in countries historically so old, may indicate the residence of man before the dawn of history. In Egypt, nodules of flint are very abundant in the Eocene limestones, and, where these have been wasted away, remain on the surface. In many places there is good evidence that the flint thus to be found everywhere has been, and still is, used for the manufacture of flakes, knives, and other implements. These, as is well known, were used for many purposes by the ancient Egyptians, and in modern times gun-flints and strike-lights still continue to be made. The debris of worked flints found on the surface is thus of little value as an indication of any flint-folk preceding the old Egyptians. It would be otherwise if flint implements could be found in the older gravels of the country. Some of these are of Pleistocene age, and belong to a period of partial submergence of the Nile Valley. Flint implements had been alleged to be found in these gravels, but there seemed to be no good evidence to prove that they are other than the chips broken by mechanical violence in the removal of the gravel by torrential action. In the Lebanon, numerous caverns exist. These were divided into two classes, with reference to their origin, some being water-caves or tunnels of subterranean rivers, others sea-caves, excavated by the waves when the country was at a lower level than at present. Both kinds have been occupied by man, and some of them undoubtedly at a time anterior to the Phœnician occupation of the country, and even at a time when the animal inhabitants and geographical features of the region were different from those of the present day. They were thus of various ages, ranging from the post-Glacial or Antediluvian period to the time of the Phœnician occupation. Dr. Dawson then remarked that many geologists in these days had an aversion to using the word 'Antediluvian,' on account of the nature of the work which, in years now gone by, unlearned people had attributed to the flood described in Scripture; but, as the aversion to the use of that word was, he thought, not called for in these days, he hoped it would pass away. Speaking as a geologist, from a purely geological point of view, and from a thorough examination of the country around, there was no doubt but what there was conclusive evidence that, between the time of the first occupation of these caves by men—and they were men of a splendid physique—and the appearance of the early Phœnician inhabitants of the land, there had been a vast submergence of land, and a great catastrophe, aye a stupendous one, in which even the Mediterranean had been altered from a small sea to its present size. In illustration of this, the caverns at the Pass of Nahr-el-Kelb and at Ant Elias were described in some detail, and also, in connection with these, the occurrence of flint implements on the surface of modern sandstones at the Cape or Ras near Beyrout; these last were probably of much less antiquity than those of the more ancient caverns. A discussion ensued, which was taken part in by a number of distinguished Fellows of the Royal Society, including Sir H. Barkly, F. R. S., Professors Wiltshire, F. R. S., Warrington Smyth, F. R. S., Rupert Jones, F. R. S.; Colonel Hirschel, F. R. S., the talented son of the late Sir John Hirschel; Dr. Rae, F. R. S., the Arctic explorer; Dr. Dawson, F. R. S.; Mr. D. Howard, the vice-president of the Chemical Institute, and other geologists."

Lectures and Addresses.

THE CARTWRIGHT LECTURES

ON

METHODS OF STUDYING THE BRAIN,

DELIVERED BEFORE THE ALUMNI ASSOCIATION OF THE COLLEGE OF PHYSICIANS AND SURGEONS, NEW YORK, FEBRUARY 2, 4, AND 6, 1884.

By BURT G. WILDER, M. D.,

PROFESSOR OF PHYSIOLOGY, COMPARATIVE ANATOMY, AND ZOOLOGY IN CORNELL UNIVERSITY, AND OF PHYSIOLOGY IN THE MEDICAL SCHOOL OF MAINE.

LECTURE III, PART II.

Methods of Illustration and Description.

THE second part of the third lecture includes the following matters:

I. Enumeration of some points in normal, macroscopic, encephalic anatomy which require elucidation.

II. Suggestions as to modes of illustration.

III. Suggestions as to terms of designation and methods of description.

IV. List of technical macroscopic encephalic terms, with some of their synonyms.

V. List of publications referred to, with a brief commentary on modes of reference.

I. In the first lecture (this journal, February 9th, p. 142) reference was made to "the not unnatural tendency of writers and teachers to ignore the necessity for more information than they themselves possess." Direct admissions that variations may occur, that more facts are needed, and that contrary views are held, are by no means too common in original publications; from compendiums and text-books they are almost wholly absent.

The consequences affect the student, the author, and the progress of science. The student feels no stimulus toward investigation, and either becomes an unceritcal plodder, doing little credit to himself or his instructors, or, upon discovering that some hiatus has been concealed, undergoes the natural reaction, runs to the opposite extreme, and doubts or denies everything. In the one case he makes no effort to create new knowledge; in the other the desire may exist, but is overpowered by an abnormal development of the destructive propensity; he is so intent upon rooting up the weeds of error that the seeds of truth are not even planted.

Against these two pathological mental conditions—*research-atrophy* and *criticism-hypertrophy*—the only natural and certain safeguard seems to be for writers and teachers (1) to draw a sharp line between (a) what they *know*, (b) what they *believe*, and (c) what they *anticipate*; between the proved, the probable, and the possible; (2) to recognize distinctly and admit freely the gaps in their own knowledge; (3) to point out the directions in which fruitful inquiry may be made.

Thirteen years ago I devoted a considerable portion of a paper (10) to the "Indication of General and Special Problems" connected with "Intermembral Homologies."

In "The Brain of the Cat" (14) about thirty points were enumerated as in need of elucidation, and the "Anatomical Technology," as stated in the preface, differs from most laboratory manuals in that "Attention is called to the incompleteness of our information upon certain points."

In accordance with the principle and the precedents above mentioned, and with the hope of arousing others to co-operate in the clearing up of encephalic obscurity, I select a few of the topics which merit further examination.

Arachnoidea.—By some writers it is still held that this membrane consists of two layers, parietal or dural, and visceral or pial; others admit only the visceral layer, and recently the existence of even this has been denied. Those who entertain the first view should give clear figures and descriptions of the lines of reflection of the arachnoid from the pia to the dura, and those who admit no such membrane at all should give some name to the membrane which any one can see bridging cerebral fissures and the intervals between the encephalic segments. Upon the supposition that this is the arachnoid, its relations to the pia and to the various interspaces are by no means fully understood; each region should be figured and described separately and in detail.

Bulbus postcornu et Eminencia collateralis.—How constantly present are these entocellian elevations? Do they exist in the primates generally?

Development of the Callosum.—In the embryo and in the lower mammals which part of the callosum appears first, the genu, the "body," or the splenium? Opposite opinions have been expressed by Flower (13, 637) and Balfour (ii, 365).

Cimbia.—Aside from the microscopic and physiological aspects of this part, it has been shown already (this journal, April 5th, p. 373) to merit fuller macroscopic consideration.

Conarium ("pineal body").—What are its exact relations with the pia and the endyma? Is the "brain sand" present in other mammals than man?

Fasciola ("fascia dentata").—What are the nature and significance of the alleged serrations? Do they disappear, as stated by Meckel (II, 465), on removal of the pia? Are they constant in man, and do they exist in other mammals? They do not appear in the cat (14, 556; W. and G., 478).

Flocculus.—Most figures and descriptions of this cerebellar appendage are unsatisfactory. Is it homologous with the lobus appendicularis, which is so large in many monkeys, in bears, and in some other mammals?

Homologies of the primatial Fissura centralis ("fissure of Rolando") and the *carnivora F. cruciata*.—On both morphological and physiological grounds the determination of the homologies of these two fissures is very desirable. The diversity of opinion is indicated in "Anatomical Technology" (502), and the alleged correspondence of the two fissures with each other was doubted and discussed before the American Neurological Association (33). Special lines of fissural inquiry are suggested in the work just named (503).

Insula ("island of Reil").—By what particular region

is this represented in the brains of other mammals than primates?

Medicommisura.—The transectional area of this is commonly represented as circular, but Henle (Figs. 36, 38, 39) makes it semicircular. What are its usual shape, size, and position? How frequently is it absent or duplicated? What is the color of its section when fresh? Does it exist in all mammals and in any immammalia? * How and at what period is it formed?

Metacelian foramina.—Is there but one Foramen Magendii, or are there three—one mesal, and two lateral? What are their precise locations and boundaries? Are they valvular, and, if so, does liquid pass either way with equal facility? How and at what period of development are they formed? Are they constantly present? For some discussion of this matter see this journal, April 26th, p. 458. Do they exist in man only, or in all primates, or all mammals, or also in other vertebrates?

Metatela.—The "roof of the fourth ventricle" is one of the "debatable grounds." In man and the higher mammals it is usually mutilated in the removal of the brain, or in lifting the overhanging cerebellum therefrom.

Plexuses.—In addition to what has been suggested in earlier lectures, there is something to be learned respecting the location and character of the metacelian plexuses, which are very inadequately described and figured in standard works.

Pons.—Is there any rudiment of this in immammalia?

Præcornu.—As shown in Figs. 55 and 56, this is continued as a rhinocoele in the cat, but not in the human brain, excepting, perhaps, at an early period. In what other mammals is the rhinocoele occluded? What is the form of the closed end of the præcornu? Is the ridge which appears near its tip in Fig. 56 constant? If so, what is its significance?

Prægeniculatum ("external geniculate body").—In the cat this is much larger relatively than in man, and forms an insensible transition from the thalamus to the Tractus opticus. The topography of this region—the lateral aspect of the mesen and dien—is rarely represented or described with sufficient distinctness, and even the admirable figures in Quain (II, Fig. 261) and Gegenbaur (D, Fig. 502) could be improved.

Rima.—The need of additional information respecting its margins and the distal end was indicated in Lecture II (this journal, April 5th, p. 376; April 26th, p. 460).

Rostrum et pedunculi callosi.—The relations of these parts to the terna (lamina cinerea), the pseudocele ("fifth ventricle"), and præperforatus ("anterior perforated space"), are not clearly shown in any work known to me. It is doubtful whether the "peduncles" are such in any strict sense of the word.

Striatum.—In what mammals besides man does the cauda extend to the tip of the medicornu?

Tenia.—What are its relations to the striatum, the thalamus, the endyma, and the vena striati? How does it terminate? In what other mammals does it exist?

Thalamus.—In addition to the doubts suggested in connection with its alleged appearance in the floor of the procele, the existence and extent of the pulvinar in other mammals are to be ascertained; also, whether the cephalad end is usually or distinctly emarginate to form the caudad wall of the porta.

The foregoing are but a few of the special points upon which observation and thought may profitably be expended. Confining ourselves to the features of the human brain that are visible to the naked eye, there are few, if any, which have been described and figured with the accuracy and fullness warranted by present interest in the organ. Comparative anatomy presents an almost unlimited field for study. Even if we accept the restrictions indicated for the medical practitioner in Lecture I (this journal, February 9, p. 147), certain generalizations as to the presence of commissures, etc., are always desirable, and not even the most prosaic of doctors can deny the interest that attaches to the determination of the real bodily distinctions between man and the other mammals—the constant peculiarities of the human brain. Some of these have been hinted at already. The entire subject is too extensive for more than mention upon this occasion.

II. *Suggestions as to Figures*.—For the most part these suggestions apply to all branches of Natural History, but with especial force to the human brain, on account of its softness when fresh, the difficulty of preserving it, the great size of the entire organ, the minuteness of certain portions, the large number of recognizable parts within a small area, the continuity of all, the contiguity of some which are otherwise associated but remotely, the intermixture of two differently colored substances, the complicated relations of the three membranes to each other, to the vessels, and to the cavities, and the preponderance of curved and oblique contours over straight lines and planes.

A. Terminal and limiting parts, membranes, and apparently atelic (functionless) parts and conditions should be distinctly shown, or the insufficiency of their representation admitted. "The little things of the brain" might well form the subject of an entire lecture. From the standpoints of physiology and medical practice, such parts as the terna, valvula, crista, conarium, hypophysis, and habena, and such conditions as the reflection of the endyma upon the plexuses, and the dorsal limitation of the porta, are of comparatively slight importance; but their morphological significance is, at least in some cases, inversely to their functional activity, and they can not be ignored without endangering the success of any attempt to understand or explain the structure of the brain.

Anatomical figures should be something more than pictures conveying a general and vague idea. Where is there an adequate representation of the relation of the diatela to the habense, and of the cephalad end of the latter? Where an intelligible figure of the tip of the rostrum and its relation to the terna? From the published figures, could any student be expected to comprehend the locations and boundaries of the "foramina of Monro" and of Magendie? The tenia is easily enough shown as a white band throughout most of its course, but where are its extremities accurately

* Other vertebrates than mammals.

delineated? Any one can see the caudate prolongation of the striatum, but representations of its termination at the tip of the mediacornu are as rare as are figures of the extremity of the filum terminale. Even so considerable a part as the flocculus is seldom figured in such a way as to display either its form or its attachment.

The avoidance of the morphological incongruities and deficiencies which are to be detected in nearly every portrayal of encephalic anatomy demands the admission of three propositions, which are mere truisms in themselves, but radical affirmations when contrasted with their almost universal non-recognition in anatomical works:

1. Every part, organ, membrane, or surface is either limited or continuous with some other part. If limited, its limits must be defined; if not, its extension must be indicated.

2. Every cavity is either open or closed. If closed, the continuity of its parietes must be demonstrated; if open, its communications must be shown.

3. Every elongated part has a middle and two extremities; not only the former but the latter must be represented.

B. Figures—original ones especially—should be multiplied and descriptions reduced. In descriptive anatomy, whether human or comparative, the text should be subordinate to the illustrations. Some treatises (Charles Bell, Meckel, Milne-Edwards, etc.) seem to have been prepared upon the idea that the description is essential and the figures merely supplementary; on the contrary, words should be employed only when pictures will not suffice—that is, for explanation, commentary, generalization, hypothesis, and manipulative directions.

In this respect little, if any, fault can be found with most recent works upon the brain. In Quain and Gray there is at least one figure for every two pages, and in Allen the ratio is yet higher.

The arguments for following such worthy examples may be summarized as follows:

1. A figure is usually a guarantee that something like the object represented has been seen, at least by the artist, and that a certain amount of time has been devoted to its contemplation.

2. The information conveyed by a figure is more real, and likely to be more lasting, than that which is expressed in words. In respect to reality and impressiveness, the sources of knowledge may be ranked as follows, in an ascending scale: (1) Description; (2) picture; (3) model; (4) object seen; (5) object handled; (6) object personally prepared. The picture is thus intermediate in value between the thing itself and a description thereof.

3. A figure, if clear and properly placed, is more readily understood than a description, and a saving of time is thus effected. It may be easier for the author to write than to draw, or even than to supervise a drawing, but his personal inconvenience or loss of time should not outweigh the gain to his readers. This applies particularly to dictionaries, cyclopædias, and journals, which are commonly read or consulted in haste. Editors and publishers would find eventual profit in offering to authors the fullest encouragement to employ illustrations so far as possible, and curtail their de-

scriptions in proportion. That it is rather the exception than the rule for such encouragement to be offered is probably due to several causes: *a*, publishing houses have always a staff of printers who must be employed, whereas the various processes involved in the making of pictures must usually be done outside at extra expense; *b*, authors too often content themselves with carelessly made copies of "stock figures" instead of insisting upon original representations of objects prepared by themselves. Hence, on the one hand, the exceptionally liberal publisher is liable to get a poor return for any allowance made for drawings, and, on the other, the exceptionally painstaking author is apt to be told that, at best, the engraving will be done if he will furnish the drawings; and, if he can not draw himself, their cost is likely to deter him from their introduction. In short, all the existing conditions work to the disadvantage of the reader, who gets but a "pennyworth of [pictorial] bread to a monstrous deal of [verbal] sack."

Before this state of things can be amended, the authors of books and papers must see clearly the importance of illustration; to paraphrase a witty saying as to the making of an index, the figures should be personally superintended by the author, even if some one else has to write the text.

4. Figures usually occupy less space than descriptions conveying an equal amount of information. This means condensation, convenience, and economy in the present, and a due consideration for our successors in the not far distant future. Exact data are not accessible to me, but no thoughtful and public-spirited person (unless he be a publisher or printer) can contemplate without concern the logical results of the present rate of literary production. Taking only medical works and periodicals, the practitioners and librarians of a hundred years hence will be embarrassed, if not overwhelmed, by the abundance of what we call riches and flatter ourselves in bequeathing to posterity. Long before that time, together with the inevitable demand that none shall enter the medical profession without the highest mental, physical, and moral basis, the would-be author may be forced to prove in advance that he has not been anticipated by others, that he has not used two words where one would suffice, and that he has written only what could not be exhibited to the eye. So, too, just as we find that, to secure in an exhibition case the maximum of glass and the minimum of frame, the chief constructor must be a glazier rather than a carpenter, in that time an establishment for natural-history publication may be directed, not by the promoted printer, but by the artist who possesses likewise the requisite executive ability. Then, too, both the value of figures and the labor of superintending their preparation may be so fully appreciated that not only will they be freely provided, but, in the case of paid contributions to periodicals, reckoned as part of the author's direct contribution.

C. Borrowed figures should be fully credited, and all modifications, whether of size or features, explicitly stated. To copy is to compliment, but unacknowledged copying is theft, and unspecified change is misrepresentation.

The ill-effects of omitting to state the source of a figure are two: 1. The originator loses credit to which he is justly entitled. 2. The reader may be seriously misled by the ap-

parent duplication of some really unique feature or the confirmation of an error. For example, in the representations of the meson of the cat's brain by Leuret (Leuret et Gratiot, Pl. V, Fig. 2), the pseudocoele ("fifth ventricle") is made even more extensive than in man, reaching almost to the splenium. The figure is reproduced, without credit or correction, in Mivart (B, Fig. 129). Whoever remarks the coincidence in respect to the pseudocoele, but fails to note that one figure is simply a copy of the other, may naturally infer that the feature in question is normal, or at least not anomalous.

On the other hand, if informed that three of Mivart's figures (125, 126, 129) were copied from Leuret, the student might conclude that the representation of the base of the brain (Fig. 128) was derived from the same source; this would be most injurious to the reputation of Leuret, for the figure in question displays several features (the size and direction of the hypophysis, the disconnected fissure on the Lobus temporalis, the relations of the pons to the trigeminus and abducens nerves) which it is safe to say never were observed in a feline brain.

Nor is it enough to give the sources of figures in a list, or in the preface, as in Huxley's "Vertebrated Animals"; so great is the labor of preparing an original figure that the acknowledgment of it should be equally as explicit as that of a verbal quotation.

Finally, in the case of modified figures, it needs but a moment's reflection to see that nothing short of an accurate statement of the nature and extent of the alteration can insure full justice to the originator.

(B) Drawings should be made as notes. In many cases an outline* drawing, even if hastily made, would convey to the maker, or any one else, at a future time more prompt and complete information than could be embodied in writing covering the same space. But the general employment of sketches, in addition to words, or in place of them, can hardly be looked for until children are taught to draw the intelligible objects about them before they are drilled in the making of the—to them—unmeaning pot-hooks of the alphabet.

D. Figures should be more frequently employed in preliminary or incomplete publication. Probably one of the reasons for the comparative infrequency of pictorial representations of normal, abnormal, and pathological structures, especially in journals, is the difficulty, often the impossibility, of preparing a detailed figure in time for publication. There are, of course, obstacles in respect to partial illustration which do not apply to partial description (as stated in Lecture I, this journal, February 16th, p. 179), but they are not insuperable. For example, the brain of the chimpanzee mentioned in Lecture II (this journal, February 23d, p. 209) is capable of at least four degrees of macroscopic illustration: 1, As to outline and the relative proportion and posi-

tion of the principal parts; 2, as to the fissures; 3, as to the other ectal features, including the mesal aspect; 4, the ental features, ascertainable by dissection. Now, it might be thought best to defer dissection of so rare a specimen for years; it might be months before it would be possible to publish a detailed account of its ectal features, or fissures, in comparison with those of other apes and man; but all these considerations need not, and did not, prevent the speedy presentation of the general outlines, involving a single point of special importance.

E. Figures should be based upon photographs. Photography enables the anatomist to (a) record the appearances of perishable specimens, or of such as are in course of dissection; (b) insure the proper perspective; (c) save time and labor upon the part of the draughtsman, and thus either reduce the cost of the drawings or render a larger number attainable.

It is seldom that a single anatomical preparation is so perfect as to display all that is needed, and yet present no superfluous parts; often, too, certain points are to be brought out with "diagrammatic clearness," others being subordinated or omitted altogether. Hence, as a rule, the photograph forms rather the basis for the completed figure, and two or more similar preparations may be required for the elucidation of all the desired features. But, as well remarked by Professor Gage (17, 443), the advantages of being able to exhibit a photograph in connection with a figure or a preparation, or in place of the latter, constitute, indirectly, an incentive toward more careful manipulation.

A chief obstacle to the employment of photographs as a basis for figures of brains and embryos has been the difficulty of supporting such delicate objects within range of the camera in its usual horizontal, or nearly horizontal, position. This obstacle is wholly removed by the photographic table devised by Professor Gage and used in the Anatomical Laboratory of Cornell University since 1873. With this the camera may be readily adjusted to any angle, and brought into a vertical position so as to cover an object lying upon cotton, or in alcohol, or even alive in water (see Figs. 1, 6, and 10, this journal, February 9, 1884).

(To be concluded.)

Original Communications.

CONGENITAL DEFORMITY OF THE HAND; COMBINED ECTRODACTYLISM AND SYNDACTYLISM.*

BY ALFRED C. POST, M. D., LL. D.,

EMERITUS PROFESSOR OF CLINICAL SURGERY IN THE MEDICAL DEPARTMENT
OF THE UNIVERSITY OF THE CITY OF NEW YORK, ETC.

November 3, 1883.—C. W. J., a healthy and otherwise well-formed young man, twenty years of age, was brought to my

* There is a general and almost unconquerable predilection for shaded drawings. However advantageous shading may be in ordinary art as an element of finished pictures, and when merely a general effect is desired, in anatomical figures correct outlines are essential, and shading should be deferred until the last; otherwise it is too apt to "cover a multitude" of inaccuracies.

* Read before the New York Surgical Society, May 27, 1884. The terms ectrodactylism and syndactylism are derived from the Greek *δάκτυλος*, a finger, with the prefixes *ἐκτρομα*, an abortion, and *σύν*, together.

clinic with a congenital deformity of his left hand, as seen in the cast herewith presented. There was absence of the index

and little fingers and of the corresponding metacarpal bones. The thumb and the middle and ring fingers were well developed, and their movements of flexion and extension were not deficient in force. The two fingers were webbed together throughout their whole length. From the normal position of the commissure, as far down as the middle of the second phalanges, the uniting medium was of moderate thickness, consisting of the dorsal and palmar integument, with loose cellular and adipose tissue. The terminal extremities of the two fingers were joined together immovably throughout their whole thickness, and the middle finger, being considerably longer than the ring finger, was necessarily bent, and could not be straightened. A single very wide nail covered the dorsal surface of the terminal extremity of the two fingers, having a superficial longitudinal groove to indicate the normal line of separation of the fingers.

The patient being etherized, I performed the following operation: I divided the cutaneous portion of the web with a scalpel, and then divided the nail and the deeper tissues with a cutting bone-forceps. There was a small amount of bony union of the terminal phalanges. After the bleeding had been arrested, I was able to bring the dorsal and palmar integument together on the side of each finger, with fine silken sutures, from the position of the normal commissure, about half way down to the ends of the fingers. I wound strips of adhesive plaster around each finger separately, and then secured the two fingers with a roller bandage to a padded dorsal splint extending from the ends of the fingers, above the middle of the forearm.

5th.—I removed the splint and applied fresh strips of adhe-

sive plaster around each finger. I then covered the fingers with lint secured by a roller bandage. As the splint was irksome to the patient, I did not at this time reapply it.

10th.—The edges of the wound had receded. The cuticle had separated from the cutis. I removed the sutures and dressed the fingers separately with strips of India-rubber adhesive plaster.

17th.—A portion of the integument of the ring finger has sloughed, and a small portion of the base of the middle phalanx is bare. The middle finger is doing well.

19th.—Directed the fingers to be dressed with carbolized vaseline, and reapplied the dorsal splint.

December 8th.—The middle finger is almost entirely cicatrized. The ring finger is in a much better condition than at the time of the last report, and the healing process is going on favorably.

29th.—The middle finger is healed. The commissure between the middle and ring fingers is entirely healed. The ring finger is nearly cicatrized. The middle finger now projects about 12 mm. beyond the ring finger.

January 5, 1884.—Cicatrization complete. Splint discontinued.

12th.—The middle finger has become somewhat distorted since it has lost the support of the splint, which was accordingly reapplied to-day.

19th.—The shape of the finger is improved. Continue splint.

Soon after the last date the patient discontinued his attendance.

The result of the treatment was entirely successful in overcoming the syndactylism. But the middle finger had been so long distorted by its abnormal fusion with the ring finger that it is somewhat doubtful whether it will ever assume its perfect normal configuration.

The combination of ectrodactylism with syndactylism in the case which I have presented is a rather unusual one; but Holmes, in his work on the "Surgical Treatment of the Diseases of Childhood," gives an illustration of a case resembling it, except that the fusion of the two fingers was not so complete, each of the two fingers having a separate nail. The thumb also was more widely separated from the fingers, standing out at right angles with the carpus. Both hands and both feet were affected with syndactylism.

In connection with the case which I have reported, I will present a few facts relating to the two varieties of malformation, which usually occur separately, but which in this patient were combined.

Ectrodactylism is more rare than syndactylism. The deficiency may involve a single finger or the thumb, or several or all of the fingers may be wanting, or may be in a state of very imperfect development. It may involve both hands or may be confined to one. Fort refers to thirty-two cases, in which the situation was indicated. Both hands were affected in twenty of these cases, the left hand in eight, and the right in four. In most cases only the fingers were wanting. In five cases the metacarpal bones also were absent. Some of the carpal bones are occasionally wanting. When the thumb and little finger are present, and the other fingers are absent, the hand has been compared with a lobster's claw.

Many cases of congenital absence of the thumb have been reported; in some of these the radius has been absent,

or imperfectly developed. The little finger is rarely wanting. Out of thirty-seven cases, the little finger was entirely wanting only in three, and in these the thumb and all the other fingers were absent. In two other cases the distal phalanx of the little finger was wanting.

Partial or entire absence of fingers has occurred in different generations of the same family, as in a remarkable instance reported in the "Edinb. Med. and Surg. Journal" for 1808, p. 252. As a general rule, when some of the fingers are wanting, those which exist have their full normal mobility and strength.

Syndactylism presents itself in two forms, viz., congenital and acquired. The congenital form may affect one or both hands; in the majority of cases both are affected. Sometimes the thumb and all the fingers are fused together. Sometimes all the fingers without the thumb. Any two or three may be joined together. When both hands are affected, different fingers may be involved in the two hands. The deformity is sometimes, but not often, hereditary. It is occasionally, but not usually, complicated with ectrodactylism or other deformities.

Syndactylism may be complete or incomplete. The complete form involves the whole length and thickness of the fingers, which have a common investment of skin, with perhaps a slight furrow, indicating the normal line of separation. In the incomplete form the uniting medium is comparatively thin, consisting of dorsal and palmar integument with more or less intervening cellular and adipose tissue. This uniting medium may extend the whole length of the fingers or only a part of their length; it may be quite narrow, or of considerable breadth. It is generally broadest and thinnest toward the distal extremities of the fingers. The fused fingers are usually of normal size and structure. When they are very firmly bound together they are apt to be smaller than in their normal state. There may be separate nails for the fingers, or a common nail of great breadth may extend over two or more fingers. The coalescence of the fingers may be almost complete, even involving the bony phalanges. The superficial palmar arch has been known to extend below the level of the normal commissure of the fingers. Bernier, of Besançon, reports a case in which a child was born with the thumb and four fingers all confounded, so as to constitute but one body, of the full breadth of the hand, and having a single nail at the extremity of the dorsal surface. The five toes were in like manner joined together. Dessaix reports a similar case.

Acquired syndactylism is the result of adhesion of two or more of the fingers by means of cicatricial bands following burns, or very severe mechanical injuries.

Many cases of syndactylism, whether congenital or acquired, are capable of being cured by a surgical operation. Where the fingers are all fused together in a common mass, as in the cases reported by Bernier and Dessaix, little or no benefit as to appearance or function is to be expected from treatment. In those cases of complete fusion, where only two or three fingers are involved, there is a better chance of success from an operation. Velpeau and Verneuil object to an operation where there is bony union. Fort objects to an operation when the fusion does not ex-

tend beyond the proximal phalanges, on the ground that in such cases the deformity and functional disturbance are but slight. When the thumb is fused with the index finger, an operation is especially important to the function of the thumb. When all the fingers are joined together by a cutaneous web, their separation is of less importance to function than to appearance, and, even in such cases, serious difficulties are sometimes encountered in the attempt to separate them. The general principles of treatment are the same in congenital and acquired syndactylism.

There is a difference of opinion among surgeons as to the most eligible time for an operation in congenital syndactylism. Chelius recommends waiting until the age of puberty. Nélaton, Maisonneuve, and Chassaingnac recommend an early operation. Verneuil prefers the age of three or four years. In acquired syndactylism in children, Verneuil advises a delay of one or two years after the occurrence of the deformity.

Until a comparatively recent period the operations which were performed for the relief of syndactylism were successful in a very limited degree, except in cases in which the uniting medium was broad and thin. The older surgeons contented themselves with a free division of the uniting medium, and the interposition of lint, bandages, or plasters between the fingers until the wounds were healed. The consequence was the healing by granulation and cicatrization, and the reunion of the lateral surfaces of the fingers with each other to a considerable extent below the normal commissures. And, for some time after the healing of the wounds, the persistent contraction of the cicatricial tissue caused the newly formed commissures to descend more and more toward the distal extremities of the fingers. In cases where the uniting medium is thin and broad, this retrocession of the commissures may be prevented by great care in the dressing of the wounds. After incising the web, or uniting medium, the edges of the integument of each finger should be closely approximated by strips of adhesive plaster throughout their whole extent, great care being taken to make firm pressure as close as possible to the newly formed commissure, which should be a little higher up than the normal separation of the fingers. The dressings should be frequently repeated, the parts being washed each time with a solution of mercuric bichloride, eight grains to the pint. The growth of granulations should be restrained by the frequent application of nitrate of silver, and the wounds should be sprinkled with subnitrate of bismuth. When there is an obstinate disposition to the growth of granulations from the space between the fingers, in addition to the means which have been mentioned, an elastic band may be applied between the fingers, and its two ends attached before and behind to a bracelet which is worn around the wrist. By this means any required degree of pressure may be maintained to repress the growth of granulations. In cases in which any considerable difficulty in overcoming the deformity is apprehended, it will be advantageous to establish one interdigital space completely before attempting the establishment of another. In this way pressure can be more advantageously maintained to approximate the edges of the wounds, and a more

abundant supply of material can be obtained to close the vacant spaces on the borders of the fingers.

When the uniting medium is very thick and narrow, advantage will be derived from making the incision encroach a little on the dorsal and palmar surfaces of one of the fingers, so as to leave a more ample supply of integument for the other. By this means the edges of the wound on the second finger may be healed by the first intention; and, although the healing of the other wound will be retarded, there will be no tendency to the re-establishment of lateral union between the two fingers. The healing of the wound which is left to granulate may be accelerated by skin-grafting.

Occasional instances of congenital syndactylism have occurred in which there was a small hole through the uniting medium just below the position of the normal commissure, the hole being lined with integument. In such cases, after division of the uniting medium from the perforation to the distal extremity, and separate dressing of the fingers, there is no tendency to coalescence, the skin lining the perforation being an effectual barrier to the descent of the commissure. The following case illustrates this condition, as well as the coexistence of ectrodactylism and syndactylism:

On the 23d of August, 1848, I saw a female child of Mrs. F., two months old. It was the first child of her parents, and was in good health, but deformed as follows: Right hand, thumb, and index finger perfect; the other three fingers have each only the first phalanx, and they are all webbed together throughout their whole length. The mother states that, when the child was born, a cord passed from the little to the ring finger over their truncated extremities, and that this cord was spontaneously ruptured at the age of three weeks, soon after which it disappeared. A little rudimental knob was also over the united ends of the middle and ring fingers; this also dropped off. Left hand: thumb perfect; each of the fingers has but two phalanges, the distal phalanx being deficient. The middle and little fingers each have a small pedunculated knob at the extremity. The index and middle fingers and the ring and little fingers are webbed at their distal extremities, but free toward the hand, so that a probe can be passed between them and moved freely. The middle and ring fingers are closely webbed together throughout their entire length, with the exception of a small perforation, barely admitting the passage of a probe, at the level of the normal commissure. The right foot is in its normal position, but the distal phalanx of the great toe is wanting. The left foot at birth presented a slight degree of varus, but, by the persistent manipulations of the mother, the position has been nearly rectified; the toes of this foot are all perfect.

On the 23d of August I separated the index from the middle finger of the left hand, and the ring from the little finger, bandaging the fingers separately, and on the 11th of September I separated the middle from the ring finger. The wounds all healed favorably, and the separation of the fingers was complete.

The favorable results of the operation in this class of cases, where there is a perforation between the fingers, have led surgeons to make an artificial perforation where the uniting medium was entire, and to maintain the opening by passing through it a metallic wire and leaving it in place until the circumference was cicatrized. When the web is broad and thin, such perforation is unnecessary. When it is narrow and thick, it is very difficult to secure cicatriza-

tion of the margin of the hole, and the attempt gives rise to a considerable amount of irritation. Upon the whole, I am not disposed to regard the method as one of great practical value.

Maisonneuve treated a case of syndactylism by including the uniting medium throughout its entire length between two wedges, acted on by screws so as to make pretty firm pressure, on the principle of Dupuytren's enterotome. It occasioned but little pain or inflammation. The section was complete about the twelfth day, when the fingers were found to be healed. The separation of the fingers was perfect and permanent.

Vebeau treated syndactylism by incising the uniting medium throughout its whole extent and applying three sutures at the commissure—one in the middle and one on each side.

Verneuil modified the practice by applying sutures along the whole lateral surfaces of each finger. Follin, Huguier, Morel-Lavallée, and Vidal de Cassis report successful cases treated in this way.

Fort gives a description of a variety of plastic operations devised by different surgeons for the cure of syndactylism.

The process of Zeller is as follows: A triangular flap of dorsal integument, with its base at the commissure and its apex at the articulation of the first and second phalanges, is cut and reversed on the dorsal surface of the hand. The web is then divided throughout its whole length, and the flap is brought down and attached by suture to the palmar integument. Morel-Lavallée modified this process by making a palmar flap as well as a dorsal one, truncating their apices, and uniting by suture.

The process of Dieffenbach consists in dividing the uniting medium, dissecting the skin from the subjacent parts on the dorsal and palmar surfaces, and then gliding the flaps together and uniting them by sutures on the side of each finger.

The process of Decés consists in forming the commissure from the web. The fingers being separated as widely as possible, the surgeon seizes the web longitudinally between the blades of a dissecting forceps, the points of the forceps corresponding with the normal position of the commissure. An assistant holds the forceps, while the surgeon cuts on each side from the free extremity of the web to the commissure, leaving the web attached at the commissure. The fingers are separately dressed, and heal by granulation and cicatrization, while the web shrinks and forms a commissure. Decés had complete success with this plan in a case of syndactylism from the cicatrix of a burn in a child of eight years. The commissure appeared entirely satisfactory thirty months after the operation.

A very ingenious operation for the cure of syndactylism was devised by the late Dr. J. Kearny Rodgers, of this city. I can not give the exact date of this operation, and I am not certain whether Dr. Rodgers published an account of it. But I have a record of a case in which I repeated the operation in 1846, and I have a strong impression that Dr. Rodgers had performed the operation many years before that time. The operation consists in making a longitudinal incision on the palmar surface of one finger and on the dorsal

surface of the other, and dissecting from the subjacent parts a dorsal and a palmar flap, the palmar flap covering the side of the finger from which the dorsal flap was taken, and the dorsal flap covering the side of the finger from which the palmar flap was taken. In this way the lateral surfaces of the fingers were covered with sound skin, and the wounds left to heal were transferred to the palmar surface of one finger and the dorsal surface of the other. In the case in which I performed the operation there were partial sloughing of the flaps, troublesome secondary hæmorrhage, and a considerable amount of inflammation. The healing process was retarded, and was not completed until about three months after the operation. The fingers were well separated from each other, but their motions were not very free when the child was taken from the city.

One of my colleagues in the New York Hospital undertook the performance of Dr. Rodgers's operation on an adult patient, but made the singular mistake of making the dorsal and palmar incisions on the same finger, leaving that finger only half covered with integument, while the adjacent one had a superabundant covering. The result was very satisfactory. The wound of the finger which was amply supplied with integument healed very promptly, that of the other finger healed very slowly, but there was no raw surface on the other finger to which it could adhere, and the syndactylism was completely cured.

M. Fort gives an accurate description of Dr. Rodgers's operation, illustrated by wood-cuts, but he makes no mention of Dr. Rodgers. He ascribes the operation to M. Didot, of Liège, in Belgium. Didot published an account of the operation in the "*Bulletin de l'Acad. de Bruxelles*," in 1850, tome ix, No. 5. Sédillot says that Didot reported successful cases in 1845.

There seems to be no reason to doubt that Dr. Rodgers was the originator of this operation, and that he performed it a number of years before Didot. It does not appear certain whether Didot had become acquainted with Dr. Rodgers's operation. If he had not, it is remarkable that he should have devised an operation agreeing with that of his predecessor in all its minute details.

Nélaton professes to have anticipated Didot in this operation.

In the "*Medical Press and Circular*" of April 25, 1866, Barwell describes an operation which he performed with success for the cure of syndactylism. He divided the uniting medium close to the side of one finger, so as to leave ample integument to cover the other finger; and he cut a flap from the side of the gluteal region to cover the denuded side of the first finger, binding the forearm and hand to the body until the flap had united with the finger.

The most valuable collection of facts in relation to ectrodactylism and syndactylism is to be found in a monograph entitled "*Des difformités congénitales et acquises des doigts, et des moyens d'y remédier*." Par le Dr. J. A. Fort, Paris, 1869.

COPPER AND VINEGAR PICKLES.—The report of a chemical analysis of a number of specimens of ordinary pickles, recently submitted to the Board of Health, shows that copper was present in from 9 to 2 parts in 100,000.

A CASE OF CONGENITAL WEB OF THE VOCAL BANDS.*

By THOMAS AMORY DE BLOIS, M. D.,
BOSTON.

THE following case of congenital web occurred in the dispensary practice of my colleague, Dr. J. W. Farlow, of Boston:

Louisa T., a young girl of twenty, came to the Boston Dispensary during the summer of 1883 for treatment for her throat. Her voice was exceedingly weak, hoarse, and puerile, and, although generally well developed, she stated that it had always been so; that in infancy her shrill, peculiar cry had been often remarked, but that no one was aware of the cause, nor had any laryngeal examination ever been made.

FIG. 1.—THE LARYNX BEFORE OPERATION, SHOWING THE CONGENITAL WEB.

Upon examination of the larynx, a very dependent epiglottis was seen, and it was only with the greatest difficulty that the patient was able to raise it sufficiently to allow the operator to see behind and under it. When this, however, was finally accomplished, it was seen that the anterior half of each vocal band was spanned across by a white and almost transparent web, perfectly symmetrical in all its aspects.

This membrane appeared to be elastic, and to expand and contract perfectly in unison with the motion of the vocal bands. The education of the patient was immediately commenced, for she was so intolerant that it was impossible to introduce any instrument into the larynx. This was continued during the month of August, by the end of which time she became much more tolerant.

About the 1st of September, however, Dr. Farlow was obliged from illness to give up his dispensary service, and he very kindly turned this most interesting case over to me. A lapse, however, of a fortnight had passed during which there had been no education, and, consequently, for the first two sittings I never even saw the larynx.

This condition, by constant work at my office, was somewhat remedied, and it was occasionally possible to introduce an instrument behind the epiglottis.

There being no cutting dilator nor other instrument of the kind procurable in Boston, by the advice of Dr. Knight I tried the plan of introducing a pair of Mackenzie's forceps, closed, into the larynx, with a view to opening it subsequently when the web had been passed, and thus tearing it.

FIG. 2.—THE SAME ON NOVEMBER 9, 1883, SHOWING THE WEB IMMEDIATELY AFTER ITS RUPTURE.

* Read before the American Laryngological Association, May 12, 1884.

There were many, many failures. Once I felt sure that I had split it, but found that I had only scratched it, causing some little hæmorrhage. Even after Dr. Farlow returned to his work I occasionally saw the patient at my office, and on one of these occasions, November 9th, was so lucky as to get the forceps fairly down into the trachea, and, opening it fully and withdrawing it, found that I had split the web across, leaving a "jagged," dentated edge on either band.

FIG. 3.—THE SAME ON NOVEMBER 10TH, SHOWING THE WEB WITH THE RUPTURED EDGES APPARENTLY JOINED TOGETHER.

The following day I saw the patient and found, to my dismay, that during the night the two halves of the ruptured web had apparently healed together. Certainly the voice, which immediately after the operation became low-pitched and hoarse, had resumed its former high key.

On November 11th I was able to break up the adhesions with a probe, so that the cords were almost normal in appearance, except that the edges still showed some remains of the web. This treatment of expansion was continued by Dr. Farlow occasionally.

About a month after this I saw the patient. Her larynx was almost normal, except that the vocal bands appeared to be fused together at the anterior commissure. The voice, although not very clear, was about what you would expect to find in the ordinary girl of her age. The singing voice, as tested by Dr. Farlow, had gained three notes above and four below what she was able to sing before the operation.

FIG. 4.—THE SAME ON NOVEMBER 13TH, SHOWING THE CONDITION OF THE LARYNX AFTER THE ADHESIONS WERE BROKEN UP WITH A PROBE.

The bibliography of the subject is meager, there being, I believe, but three preceding cases on record.

Zurbelle ("Berlin. klin. Wochenschr.," December, 1869, p. 544) reports the case of an eleven-year-old boy who, as an infant, had never cried, and had learned to talk late. There was a membrane between the false cords about two thirds of the length of the chink; below this there was a second membrane projecting from the ventricular sinus and resting on the true vocal cords. After some weeks' preparation, the upper membrane and one third of the lower were split with the unconcealed probe-pointed knife. Fixation of the larynx was impossible, as the boy was restless. Several days afterward the rest of the second membrane was split. Local hæmorrhage was considerable; reaction slight. The voice was very much improved. Some fragments of the second membrane were visible at the anterior commissure; the rest had completely retracted into the sinus. The voice was absolutely normal.

Elsberg ("Trans. of the Am. Med. Assoc.," 1870, p. 217).—Miss S. K., aged seventeen, had a thin, feeble voice, hoarse, high-pitched, and husky. No syphilis. The vocal bands through their whole extent were covered by a membrane which occluded the rima glottidis between them in such a way that there was but a small opening posteriorly when the vocal bands were stretched to their full extent. This opening was irregularly circular, measuring only three lines in diameter. It seemed firmly united to the upper surface of the vocal bands. When they were approximated, the membrane was folded down so as to disappear from view. This membrane was cut in two operations, by a concealed laryngeal knife, after Tobold. The membrane, being very tough, was pierced with difficulty. After the operation, the patient complained of too much air in the chest, and, by inhalations of tannin and persulphate of iron, the shreds of membrane gradually contracted. The voice became louder and more normal.

Dr. Scheff, of Vienna ("Allgemeine Wiener med. Zeitung," July 9, 1878).—The patient was a baker's boy, twenty-two years old, in whose larynx there was a web-like membrane occupying the anterior two thirds of the rima glottidis, leaving an oval opening. This web was under the free edge of the true cords, and began at the anterior commissure. There was no trouble with respiration, but the voice was hoarse.

An attempt was made to cut first with a blunt-pointed concealed knife, which was not successful. Then local anesthesia was used, and with a concealed knife a cut in the posterior edge of the membrane was made, followed by emphysema of the neck. On another occasion, with a concealed knife, another incision was made, and the edge touched with nitrate of silver. Then small pieces were removed with the forceps, etc. Although the web was entirely removed, the voice continued hoarse, owing to the treatment, and the patient disappeared before he regained his voice.

DISCUSSION.

Dr. HARTMAN questioned the advisability of the introduction of a pair of lateral forceps into the larynx, and its forcible expansion, and would prefer the covered or tube bistoury, or the galvanic cautery, for the division of webs.

Dr. ARON.—Pertinent to Dr. De Blois's case is one that I have seen in my practice. I found a web occupying the anterior portion of the glottis, the result of acute inflammation. The patient, a teacher, had had no laryngeal trouble until, after a severe attack of acute laryngitis, she lost her voice. She then lived in England. She married and removed to Central America. Her health always remained poor after the laryngitis. Last summer she came to New York for treatment, having been sent with a diagnosis of laryngeal phthisis. A laryngoscopic examination showed the web as described. There was also a vertical web in one eye, stretching from the palpebral to the ocular conjunctiva, the result of acute ophthalmia. Her voice was weak. In consequence of her feeble condition, she declined to allow me to resort to operative procedures, which, apparently, could easily have been performed.

Dr. KNIGHT.—I saw this case with Dr. De Blois, and, in reply to Dr. Hartman, I wish to justify myself for having recommended the treatment adopted. The web was very thin, even transparent, and I believed that anything introduced into the larynx would cause its rupture with the least effort and without the slightest danger to the larynx. I must say that, so far as my experience goes, it would teach me that the galvanic cautery should not be used in the larynx, and, if I mistake not, most gentlemen who have employed it there have abandoned it, because of the danger attending its use at so great a depth.

Dr. DE BLOIS.—I do not think the account of the difficulties

of the operation was fully appreciated by Dr. Hartman. When you have a patient who only about once in ten sittings is able to give any view of the vocal cords at all, and in whose case whatever instruments are introduced must be introduced at random, I can hardly think that the use of either the knife or the galvanic cautery would be justifiable. This web was quite thin, as Dr. Knight says, but I stretched it several times before it finally tore. It was tougher than I had anticipated. I do not know what danger Dr. Hartman would expect from the use of the forceps in a case of this kind. I do not see how it could do any more violence to the parts than cutting and the use of the dilator would. The woman menstruated normally, and there was no other explanation for the peculiarity of the voice than the abnormal condition in the larynx.

TWO CASES OF CHANCER OF THE TONSIL.

By CHARLES H. KNIGHT, M. D.

THE reading of a paper on "Chancer of the Tonsil" at a recent meeting of the Academy of Medicine has led me to review the case-books of the late Dr. Bumstead for histories of tonsillar chancre. The records cover a period of twenty-three years, and include a great variety of cases in both hospital and private practice. The results of my search seem to support the belief that chancre of the tonsil is of rare occurrence, since I have been able to find only two cases:

CASE I.—The first case was seen by myself only once or twice, and the history was taken by Dr. Bumstead. I presume this is the case referred to by Dr. R. W. Taylor, in his paper at the Academy, as having been described to him by Dr. Bumstead. The patient was a young man, about thirty years of age, who developed a chancre on the left tonsil sixteen days after "abnormal coitus." This was followed within three weeks by engorgement of glands beneath the jaw on the left side, a general eruption of roseola, and, a few weeks later, by enlargement of the post-cervical glands and mucous patches of the scrotum. At the time he was first seen the ulcer of the tonsil had existed nearly a month and was in process of repair; no induration of its base could be detected. There seemed to be no question as to its character.

CASE II.—Owing to Dr. Bumstead's ill-health, the second case was under my exclusive observation after the first visit. The circumstances preclude the possibility of willful deception on the part of the patient or of her physician, from whom the details were obtained, and its authenticity was fully accepted by Dr. Bumstead. The patient was a married lady, about forty years of age, who presented an ulcerating gumma of the right leg, just above the external malleolus. The history of the primary sore, contracted twelve years previous, and of the subsequent manifestations, runs as follows: "Sore throat" was complained of, for which she consulted her physician. In a few weeks an eruption of macules and papules appeared upon her chest and neck, accompanied by enlarged cervical glands and cachexia. The nature of the ulcer of the tonsil, which had not yet healed, was now for the first time suspected, and improvement in all the symptoms followed the adoption of specific remedies. Several relapses of the cutaneous lesion occurred, which promptly yielded to mercurial treatment. No new symptoms appeared for several years, when the gummy tumor of the leg developed. Mercury was ineffectual, and, owing to her extreme intolerance of potash, the patient was unable to take the

latter drug. In consequence, the tumor was very chronic; it finally subsided, but reappeared in the course of six months.

This case is of interest, not only from the location of the chancre, but also from the striking effects of even a single small dose of iodide of potash. A few minutes after taking five grains of the drug she complained of nausea, intense frontal headache, photophobia, increase of salivary secretion, and a peculiar feeling of constriction in the throat. Three grains of iodide of sodium, thoroughly disguised, were followed in about an hour by similar symptoms. The patient was not hysterical, and was very anxious to take potash, being convinced that it would be of benefit. It was finally given in the form of a two-grain sugar-coated pill, of the ingredients of which the patient was unaware. No unpleasant effect followed, and in the course of a month she was able to take a drachm a day without discomfort. Under its influence, the undermined edges of the ulceration having first been freely divided, rapid healing took place, and no recurrence has been noted up to the present time.

This lady is believed to have derived her chancre from her nephew, a boy of sixteen, who was in the habit of visiting her room and "making use of her tooth-powder." It is known that he was at that time suffering from buccal mucous patches and other syphilitic symptoms. No other relative or friend of the patient is known to have had syphilis, and her own character is irreproachable. The history of this case also shows the occurrence of syphilitic hypertrophy of the tonsils, which has been minutely described by Paul Hamonic in the "Annales de dermatologie et de syphiligraphie" for July and August, 1882, and observed by Morel-Lavallée in an interesting case of chancre of the tonsil reported by him in the same journal for January, 1883. In this instance the ulcer seems to have presented many of the features of a typical syphilitic chancre, but no reference is made to the occurrence of induration of its base. On the contrary, in a case reported by A. Hue, in "La France médicale" for May 31, 1883, marked induration of its base was recognized, while the chancre had no other characteristics commonly attributed to the primary sore. In every case, however, thus far reported, early induration of neighboring ganglia has been observed before the outbreak of a general adenopathy. This phenomenon would seem to be about the only reliable diagnostic sign, and, if this be absent, a suspicious ulcer of the tonsil may have no reason to be considered an "infecting chancre."

AN ENTOZOON IN THE TISSUES OF THE PIGEON.*

By PROFESSOR SAMUEL LOCKWOOD, PH. D.,
FREEHOLD, N. J.

IF the entozoa which afflict animal life were divided into two groups—those which infest the alimentary canal, and those which burrow into the living tissues—of two evils we might much more dread the burrowers. These fearful little carnivores have no respect for place; the muscular tissue may swarm with them, and the sufferer be eaten up with what seems to him a strange, burning inflammation or fever. Nay, these microscopic monsters often have a penchant for the veriest seats of agony, penetrating and making revelry

* Read in abstract at the April, 1884, meeting of the New Jersey State Microscopical Society.

in some vital organ—the heart, the eye, or the brain. Those occupying the alimentary canal may be reached by medical skill, but these burrowers into the life tissues defy all comers. It is to be feared that the burrowing entozoa are increasing. In 1869 I read some notes before the New York Lyceum of Natural History (New York Academy of Sciences) on an entozoon which I had discovered imbedded in the adipose tissue on the entrails of the common eel (*Anguilla vulgaris*). In November, 1871, I read to our society a paper involving a more complete study of the subject. The substance of that paper appeared in the "American Naturalist," August, 1872, under the title, "A New Entozoon from the Eel." There was given a diagnosis of the genus and species, with the new name, *Koleops anguilla* (Lockwood). At the meeting of this society in June, 1873, I read a letter to myself from Professor F. H. Welch, F. R. C. S., of the Royal Victoria Hospital, Netley, England. The writer was the author of an interesting article in the "Lancet," in February, 1873: "The Presence of an Encysted Echinorhynchus in Man." This genus belongs to the *Acanthocephala*, or spiny-headed worms—that is, those having recurved hooklets around the proboscis. This was a characteristic of *Koleops*, and the professor expressed his conviction in the letter that this group of worms would prove common in fishes. The subject of his paper in the "Lancet" was obtained from the dissection of a soldier returned from India. He said it was quite probable that many would be found in the bodies of soldiers.

Since that time, in its progress, helminthology has shown a number of these tissue-boring pests, the most notorious of the list being the pork pest, *Trichina spiralis*. It is so because of its great numbers; otherwise it is of small moment as compared, for instance, with the screw-worm, which is not a helminth.

I have in this small phial two specimens of entozoa which were taken from an adult pigeon, and sent me by Professor C. R. Barnes, of Purdue University (Department of Natural History), Indiana. They are very minute, and in every way microscopic. They were found "imbedded in the connective tissue investing the jugular vein, near the juncture of the branchial." The date of Professor Barnes's letter is March 15th; hence it is a coincidence to find in the "American Naturalist" of this month a note of the discovery of the same species. I had failed to determine it. From Professor Garman's note I have no doubt this is an early larval stage of *Pterolichus falciger* (Megnin), the *Hypoderas columba* (Murray). Garman says he has noticed this mite on several occasions in the tissues of the domestic pigeon. "As stated by Robertson, it occurs most abundantly in the connective tissue about the large veins near the heart; but a few may be found under the skin in the region of the arm-pit." It is about 1.5 mm. long. Garman says: "No mouth parts are visible; . . . it is safe to assume there are none." I have no comment to make on this, but must state a fact which caused me great surprise.

The pigeon from which these specimens were taken was a male bird that had been kept for a day in fifty-per-cent. alcohol. These larvæ were sent me in seventy-five-per-cent.

alcohol, and I should think, ere I looked at them in the microscope, that they had been in this fluid four or five days. I noticed a crater-like depression, the edge being slightly puckered, suggesting to me a sucking ring. While looking, to my astonishment, up rose from the bottom of this crater a petiolate body, with a knob on top; in the center of this knob, at its flattened face, was a distinct oral pore. It really seemed that this crater edge had a sucking power, and that the little club, with its oral pore, was the real mouth. But the amazing fact was the presence of vitality. The little organ retracted and projected itself with a slow but perfectly rhythmical movement, until, the alcohol evaporating, it ceased. I applied a drop of water, but the spasmodic life-force was spent. However, there was this gain left. When I first looked into the crater, this little organ was unseen. Now it had died, with itself partly projected, allowing me some time to examine it. On curative considerations, this vitality of parasites has a fearful significance.

But, though playing the rôle of entozoa, these little scourges are not helminths or true worms at all. The bot-worm and the screw-worm, so called, are the larval offspring of the diptera, or true flies. But our pigeon parasite is the larva of a burrowing mite, or hexapodous louse.

A CASE OF

ZOSTER FOLLOWING TRAUMATISM.

By HENRY LING TAYLOR, M. D.,

NEW YORK CITY.

ON March 5, 1884, there came to the Roosevelt Hospital, out-patient department, a man, aged twenty-four, single, and a driver by occupation, who gave the following history: While working, March 1st, a barrel weighing about twenty-five pounds fell upon his left shoulder from a height of ten feet or more. The injury was not sufficiently severe to cause him to quit work, but the next day his shoulder felt somewhat sore and stiff, and he noticed a small lump on the left side of his neck. During the evening of March 2d he had a sensation of prickling on the left side of the neck and of the back of the head, and along the left side of the body of the inferior maxilla. This had continued to the date of examination. On the morning of March 5th he had noticed several clusters of small blisters on the left side of the neck. Examination showed a very painful and tender area over the left half of the occipital bone and left side of the neck, with groups of vesicles scattered over this region from the median line behind to that in front. The lump spoken of seemed to be an enlarged gland. The diagnosis of zoster was confirmed by my colleagues in the dispensary. Ung. zinc. oxid. was ordered. When the patient called, March 7th, the eruption had made great progress. The skin was very red and fiery, there was considerable swelling, and the neck was held very stiff. The vesicles had increased in size and number, and new patches had appeared. The eruption was semi-confluent in parts. It then extended along the lower border of the jaw and behind and in front of the left ear, and downward to below the clavicle and to the same level behind. The patient suffered intensely from burning pain. Tongue coated. Ordered lead-and-opium wash and a laxative.

March 10th.—Pain relieved rather suddenly last night. Some of the vesicles are very large and filled with sero-pus.

14th.—Eruption is now dried down and scabbed, and there

is no pain. The scabs in the hair reach to the top of the head. There is little swelling, and the neck is moved quite freely.

21st.—The only remains of the eruption are the scabs, but there are some indurated points beneath the skin; three of these are incised, and a drop or two of thick pus is expressed. Ordered a poultice and ung. zinc. oxid.

31st.—Skin nearly normal. There are still a few very small subcutaneous nodules, yielding a drop of thick pus on incision.

There appears to have been a traumatic neuritis of the cervical plexus on the left side, causing a zoster of unusual severity in the skin areas to which the nervous filaments are distributed, and also circumscribed areas of cellulitis, which ended in places in the formation of small nodules containing pus.

Book Notices.

Die einfache chronische Exsudativ-Peritonitis. Von Dr. HERMANN VIERORDT, Privatdocent, etc. Tübingen: H. Laupp, 1884. Pp. 141. [Price, \$3.]

This monograph contains an interesting description of a class of cases that have received but very little attention in text-books. The author says that he undertook the work, not so much with the view of describing a new disease as with the purpose of systematizing the clinical and pathological knowledge already at hand concerning a well-known though often obscure affection. The morbid anatomy consists essentially in a simple exudative peritonitis, which, uncomplicated, manifests no special tendency to a fatal termination; indeed, the number of post-mortem examinations has been small. The author gives the clinical histories of twenty-eight cases, of which by far the larger portion occurred either in children or in young adults, and among females. He adopts Galvani's plan of description, and speaks of the period of prodromes, the period of exudation, and the period of resorption. The first he regards as difficult to make out; the predominant symptom of the second is ascites; and after the third there is left a feel of knotty conglomeration, which is due to agglutination of the coils of intestines into a more or less compact mass, the intestinal tube itself remaining pervious, and the patient living for years perhaps, as with the remnants of a pleurisy or a pericarditis.

The affection has been ascribed to a great number of causes, which in some cases are exceedingly obscure. Among those assigned, the more common are exposure to wet and cold; acute diseases, such as typhoid fever and measles; traumatism, pregnancy, diarrhoea, and gastric ulcer. Some cases are recorded as idiopathic. Of course, tuberculosis and syphilis have a place in the etiological group, but not a prominent position, and there is special room for the opinion that those cases in which peritonitis is due to the former belong to another class, and not to the one under consideration. No therapeutical measures seem to have acquired very great repute, notwithstanding the use of a large number of them, and also the fact that a high percentage of the patients escaped from immediate danger, while many recovered entirely.

The monograph is a welcome addition to medical literature.

A Manual of Pathology. By JOSEPH COATS, M. D., Pathologist to the Western Infirmary and the Sick Children's Hospital, Glasgow, etc. With 339 Illustrations. Philadelphia: Henry O. Lea's Son & Co., 1883. Pp. xxi-19 to 818.

In this manual it has been sought to give an advanced exposition of morbid anatomy, and to make the complicated phe-

nomena of disease intelligible in their statical and dynamical aspects by ample theoretical considerations. The leading sections on general and special pathology are prefaced by short descriptions of normal functions and structures, and to these descriptions references are repeatedly made in the exegetical portions of the text. To diseases of nervous structure, for example, we are introduced by a summary review of the fundamental anatomical and physiological relations of the nervous system, and the properties of normal substance as affected by morbid changes; and the special pathology of the spinal cord and the brain follows an examination of the manner in which the special functions of those organs are connected with special structural details. Here we find incorporated the very important conception of Ross and Hughlings Jackson that the accessory portions of the nervous system are more liable than the fundamental portions to undergo retrogressive changes.

In an admirable account of the pathology of diabetes, the data are employed to give support to the vaso-motor theory of Dr. Pavy. "All the facts," we are told, "may be held as indicating that diabetes depends on the liver being supplied with blood of an abnormal character at an accelerated rate of speed. The congestion of the liver depends on abnormal nervous arrangements, and these may be local, affecting the coeliac plexus, or possibly situated in the central nervous system." As elsewhere, the author here indorses views of, to say the least, a very speculative character, the immaturity of which quite disqualifies them for a place in a work destined to be extensively used as a text-book.

The matter is well arranged for reference, and, except for a somewhat monotonous repetition of phrases, the work is deserving of praise in point of style. The illustrations are abundant, many of them are original, and they are all perspicuous and well chosen. On the whole, the book is one of distinctive and in many respects unsurpassed merit.

The Pathology, Diagnosis, and Treatment of the Diseases of Women. By GRAYLY HEWITT, M. D. Lond., F.R.C.P., Professor of Midwifery and Diseases of Women, University College, and Obstetric Physician to the Hospital, etc. A New American from the Fourth Revised and Enlarged London Edition. With 236 Illustrations. Edited, with Notes and Additions, by HARRY MARION-SIMS, M.D., Attending Surgeon to St. Elizabeth's Hospital, New York, etc. New York: Bermingham & Co., 1883. Two Volumes. Pp. 20-33 to 469; 14-17 to 561. [Price, \$4.50.]

PROFESSOR HEWITT's work long ago became one of the standard text-books, and there is now no occasion to say more of it than that it is a book which no student of the subject ought to omit reading, although he should bear in mind that it reflects the views of an extremist in the matter of the mechanical element in uterine pathology. The American editor's notes to this edition are few, but they are of a character to add to the value of the volume, while they give a very fair picture of much that is peculiar to American gynecology. The publisher's work has been well done in the main, but the illustrations are not so clearly printed as we are accustomed to see in most of the medical books of the present time.

THE
NEW YORK MEDICAL JOURNAL,
A Weekly Review of Medicine.

Published by
D. APPLETON & CO.

Edited by
FRANK P. FOSTER, M. D.

NEW YORK, SATURDAY, JUNE 14, 1884.

RODGERS'S OPERATION FOR WEBBED FINGERS.

ONE of the most gifted of American surgeons, the late Dr. J. Kearny Rodgers, is credited by Dr. Post, in the paper on syndactylism and ectrodactylism published in this issue of the journal, with having been the first to suggest the ingenious plastic operation for the relief of the first-named deformity which is commonly attributed to the Belgian surgeon Didot, being the procedure of making longitudinal palmar and dorsal incisions on alternate fingers, and covering each with a flap formed by reflecting the skin so as to separate the dorsal from the palmar layer of the web. Dr. Post considers it uncertain whether Dr. Rodgers ever published an account of the operation, and a somewhat superficial survey of the literature of the subject has failed to furnish us with any evidence that he did. It is quite likely, therefore, that Didot, whose description of the operation was published, unless we are mistaken, in 1849, would continue to be regarded as without question the originator of the procedure, especially as Sédillot states that he reported cases in 1845, were it not for Dr. Post's personal recollection to the effect that Dr. Rodgers had performed the operation many years prior to 1846, the date of a case in which Dr. Post has the record of his having done it himself. Even with this testimony, it may not be easy to satisfy the world at large that Didot was anticipated by the New York surgeon; but Dr. Post's statement is assuredly sufficient to warrant us in this country in assigning the credit to Dr. Rodgers.

It is quite conceivable, of course, that the two men hit upon the device in question independently of each other, for such coincidences have happened again and again, but, as Dr. Post remarks, it is not a little singular that the details should have tallied so exactly. Even if it is positively settled that no account of Rodgers's operation was published in this country prior to the reports of Didot's first cases, it does not absolutely prove that the latter surgeon arrived at the method as the result of independent thought, for Rodgers was a surgeon of great local fame, connected with what was at that time the only large hospital in New York, and his operations were likely to be made the subject of talk among persons who may afterward have been thrown with Didot; there is, therefore, no inherent improbability in the suggestion that a verbal account of his method of operating for the relief of webbed fingers may have reached Didot, who, in turn, may have really forgotten the source of the idea at the time he published his first cases. In the absence, however, of anything to prove that this was the case, it is but just to credit him with originality, if not with priority.

Rodgers died many years ago, and it may be questioned if

any one now living feels a personal interest in establishing a tribute of this sort to his memory, but the credit of American medicine is made up of what is accorded to individuals, and, from this point of view, it is exceedingly satisfactory that so precise and conscientious a man as Dr. Post feels justified in giving currency to the statements to which we have alluded.

THE CLOSE OF THE NEW YORK SOCIETY SEASON.

THE Medical Society of the County of New York having voted to omit its June meeting, and the Academy of Medicine having decided not to hold its second meeting for June, the local society season may practically be said to have come to a close, although the County Medical Association (which should not be confounded with the society first mentioned) will hold a meeting next week, and some of the private societies are still to meet once before the summer vacation. These omissions of meetings have not been decided upon because there remained nothing more to be done, and it is still more satisfactory to be able to add that they have not been resolved upon as a makeshift to allow acrimonious feelings to cool off, as was the case with the Academy of Medicine a year ago; but simply because it is getting to be felt more and more that evening meetings during warm weather do not, on the whole, further the work of the year. And, surely, enough has been accomplished during the season now closing to justify the indulgence in a four months' respite.

Reviewing the winter's work, we think it must be said that it has been exceptional in several respects. As a whole, it has been much more extensive and much more profitable than has generally been the case in New York, as we think our columns for the past six months will bear testimony. We have been able to give society papers in unwon number, and the space we have felt obliged to devote to the reports of discussions has been greater than in former years. In order to present these papers and discussions with the promptness that the circumstances called for, we have had to delay the publication of some contributed articles, and we take this occasion to assure their authors that we appreciate the forbearance shown by them in the matter.

The work of the season has been remarkable in this respect also, that the best of it has been done in the large public societies, and not, as has generally been the case, in the special private bodies. It will not be thought invidious, we feel sure, if we add that the Academy of Medicine has borne off the honors for the papers and discussion on puerperal fever which occupied two of its meetings were of so high an order of merit, and so enlisted the attention of the profession throughout the country, that in themselves they might have counted for a fair winter's work. Moreover, with barely an exception, the other papers read before the Academy have been of such a character as to do credit to its position before the profession. That this work is appreciated is shown by the accession of twenty-four new Fellows at the last meeting, and by the gifts of money that we have had the pleasure of recording. When we look back upon the disasters that threatened the Academy at the opening of

the season, we may say more of its distinguished president—for on him has practically rested the work—than that out of the nettle danger he has plucked the flower safety.

While thus pointedly specifying the Academy of Medicine, we are not unmindful of the creditable work that has been done by the other large societies; if their light has been somewhat dim, it has been only that it has been outshone by the greater luminary. The Medical Society of the County of New York has done well in comparison with former years, and, in extenuation of its failure to take the leading position from a scientific point of view, it should be borne in mind that it is peculiarly charged with what may be called the business of the profession. The new New York County Medical Association, which was not organized until the season was somewhat advanced, has also been the means of bringing out a number of papers of a high order.

When we say that the special societies have been outdone by those of a general scope, we do not imply that they have not kept pace with their own achievements in the past, for such is not the case; it is simply that the general societies have this year outdone themselves. We are unable to see that the causes have been exceptional, and it is to be hoped, therefore, that coming seasons will witness a continuance of their vigor.

MINOR PARAGRAPHS.

HUMOR AT A LONDON SOCIETY MEETING.

WE learn from the "Medical Times and Gazette," which, by the way, has become one of the sprightliest of our exchanges since its recent change of form, that at a meeting of the Clinical Society of London held lately a discussion took place on the subject of nephrotomy, in the course of which Mr. W. Anderson, who advocated the procedure of opening only the pelvis of the kidney, proposed for that particular form of operation the name of pyelo-lithotomy, whereupon Mr. Henry Morris "gently ridiculed" the proposition, saying that an operation involving only the calix might fitly be called "callico-lithotomy." At the same meeting a proposal to take the refreshments before the work of the meeting hereafter, instead of at its conclusion, appeared to meet with general approval. If this scheme is really put into operation, what sallies of humor may we not look for in the proceedings?

AN ACKNOWLEDGMENT.

IN our issue for April 12th there appeared an editorial article entitled "Elocution in Medical Lectures," and in the number for May 3d another bearing the title of "Stretching the Spinal Cord." An English contemporary, the "Midland Medical Miscellany and Provincial Medical Journal," has done us the compliment to adopt them as its own, reproducing the former in its issue for May 1st, and the latter, except the closing paragraph, in its issue for June 2d. Although our contents are often drawn upon by our contemporaries, candor compels us to confess that those of them for which we feel the greatest respect are generally careful to leave with us the burden of responsibility for the sentiments expressed. This has not invariably been the case, however, and we feel that we ought to have made acknowledgments to some of the journals that have copied our articles without the caution alluded to. In the future we shall try, therefore, to give proper expression to our gratitude, and

we think it no invidious distinction to begin with the "Miscellany," since it has thus honored us in two consecutive numbers.

PRIVATE PRACTICE BY ARMY SURGEONS.

THE physicians of New London, Conn., are somewhat exercised over the fact that a medical officer of the army, on duty at Fort Trumbull, has thought fit to do private practice in the town, and the matter has been freely commented on in the local newspapers. We can understand that there should be some heartburnings about the practice under certain circumstances, but that an army surgeon necessarily commits any injustice, or even any impropriety, by practicing among civilians, we can not concede. By so doing he fits himself more and more for the Government service, and he encroaches no more on the province of his professional brethren than if he were to settle in the town as a civil practitioner, save for what little advantage may come to him from the *clat* of the official position. At all events, the medical officers of the army ought to be better paid if they are to be expected to refrain from practice among civilians.

THE "SWILL MILK" OF BLISSVILLE.

It is satisfactory to learn that the sanitary authorities have been able to bring a keeper of swill-fed and diseased cows to trial, and to secure his punishment by a heavy fine; but for the repute of our craft it is not so satisfactory to learn that a medical witness testified that the milk was liable to produce "scrofula, diphtheria, and blood-poisoning." It is to be hoped that the newspaper accounts are overdrawn, and that no such loose testifying was indulged in on the occasion referred to.

NEWS ITEMS, ETC.

INFECTIOUS DISEASES IN NEW YORK.—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending June 10, 1884:

DISEASES.	Week ending June 3.		Week ending June 10.	
	Cases.	Deaths.	Cases.	Deaths.
Typhus	3	0	7	1
Typhoid Fever	3	5	15	3
Scarlet Fever	57	9	72	7
Cerebro-spinal meningitis	4	4	3	3
Measles	153	28	148	25
Diphtheria	52	18	53	26

THE IMMIGRATION OF INSANE PAUPERS, a growing evil, has attracted the attention of the State Board of Charities, which has asked the co-operation of the Commissioners of Public Charities and Correction of the city in an attempt to secure legislation designed to mitigate the burden.

THE CONTAGIOUSNESS OF CONSUMPTION has gained substantial recognition in New York, if we may judge from the announcement that certain wards in Charity Hospital are to be set apart for the isolation of consumptives.

A CHINESE PHYSICIAN is reported to have been permitted by the Board of Health to register in this city, to practice among his countrymen.

THE COWS OF NEW YORK, it is stated, are to be subjected to a systematic inspection under the direction of the Board of Health, with the double purpose of aiding the Government officials in checking contagious pleuro-pneumonia and of guarding against the spread of tuberculosis by the milk of diseased cows.

A REMOVAL.—Dr. Edward W. Jenks, who for several years past has held the chair of gynecology in the Chicago Medical College, announces that reasons of a domestic nature induce him to return to Detroit, where he will re-establish his private hospital so soon as the necessary arrangements can be completed.

THE "FAITH-CURE" AND THE CHURCH.—An Episcopal clergyman sojourning in New York having declined to employ a surgeon for the relief of his daughter, who had sustained a fracture of the arm, relying implicitly, as he said, on a professor of the "faith-cure," the assistant bishop of the diocese has administered a kindly but effective rebuke, which, in conjunction with legal proceedings brought by the Society for the Prevention of Cruelty to Children, has resulted in regular medical attendance being afforded the child.

THE PROGRESS OF CREMATION is attested by a project for building a crematory at Bordentown, N. J., the idea being that it will be within easy reach of both New York and Philadelphia.

AN INOPORTUNE DISLOCATION OF THE JAW is one of the topics dealt with by a *feuilletoniste* writing in a recent issue of the "Union médicale." It seems that during the performance of a wedding ceremony the bride sneezed so violently as to dislocate her jaw at the critical moment when she should have pronounced the solemn "oui." As she was unable to articulate the word, it was found necessary for the whole party to repair to a surgeon before the ceremony could be completed.

AN UNUSUAL INJURY OF THE CEREBELLUM, as we learn from the "Medical Times and Gazette," was illustrated by a specimen shown at a recent meeting of the Pathological Society of London, by Mr. Morgan. The specimen consisted of the cerebellum and the atlo-occipital joint of a child that had come to its death by falling down-stairs at a moment when it had a knitting-needle in its mouth. The needle was driven through the palate and the atlo-occipital joint into the cerebellum, and, although it was withdrawn at once, the child died in about twenty-four hours.

AN HONOR TO AN ENGLISH PHYSICIAN.—The "British Medical Journal" states that the Queen of Great Britain has conferred the dignity of Knight Commander of the Bath on Dr. Henry Wentworth Acland, for many years the president of the Medical Council.

AMERICAN PORK now seems likely to be admitted into France after proper examination, a committee of the French Legislature having submitted a report containing a recommendation to that effect.

THE UNIVERSITY OF BERLIN.—According to the "Medical Times and Gazette," Dr. Hans Virchow, a son of Professor Virchow, heretofore a *Privat-Dozent* at Würzburg, has been called to Berlin, to take charge of the histological course, under Waldeyer, the new professor of anatomy.

ST. MARY'S HOSPITAL MEDICAL SCHOOL, OF LONDON, as we learn from the "Lancet," has added Dr. Orichton Browne to its staff of lecturers, his chair being that of mental diseases.

THE NATIONAL ACADEMY OF SCIENCES.—A bill authorizing the Academy to receive bequests and gifts, to be held in trust and used for the promotion of science, has passed both houses of Congress.

THE BRITISH MEDICAL ASSOCIATION.—From an announcement in the "British Medical Journal" we learn that at the fifty-second annual meeting, to be held at Belfast, July 29th, 30th, and 31st, and August 1st, the following addresses will be delivered: Medicine, Dr. William M. Ord, of London; physiology,

Professor Peter Redfern, of Belfast; obstetrics, Dr. George H. Kidd, of Dublin.

ARMY INTELLIGENCE.—*Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from June 1, 1884, to June 7, 1884:*

MOORE, JOHN, Lieutenant-Colonel and Assistant Medical Purveyor. Ordered to perform, in addition to his present duties, those of medical storekeeper, San Francisco, Cal.

JOHNSON, HENRY, Captain and Medical Storekeeper. Relieved from duty at the medical purveying depot at San Francisco, Cal., and ordered to report for duty at the medical purveying depot, New York city, relieving Captain Andrew V. Cherbonnier, medical storekeeper.

Captain Cherbonnier, on being relieved by Captain Johnson, will proceed to St. Louis, Mo., and report in person to Captain George T. Beall, medical storekeeper and acting assistant medical purveyor, for duty at the purveying depot at St. Louis, relieving Captain Beall of his duties as medical storekeeper. Par. 9, S. O. 128, A. G. O., June 3, 1884.

FRYE, BLENCOWE, E., Major and Surgeon. Granted leave of absence for one year, from July 1, 1884. Par. 7, S. O. 128, A. G. O., June 3, 1884.

HALL, JOHN D., Captain and Assistant Surgeon. Granted leave of absence for three months, to take effect on his arrival at St. Paul, Minn. Par. 8, S. O. 128, A. G. O., June 3, 1884.

HEGER, ANTHONY, Major and Surgeon. Assigned to duty at Fort McHenry, Maryland, as post surgeon. Par. 1, S. O. 108, Headquarters Department of the East, June 2, 1884.

HUNTINGTON, DAVID L., Major and Surgeon. During the absence of the Surgeon-General, directed to take charge of the office of the Surgeon-General and perform his duties. Par. 6, S. O. 129, A. G. O., June 4, 1884.

BENTLEY, EDWIN, Major and Surgeon. Assigned to duty at Fort Clark, Texas, as post surgeon. Par. 1, S. O. 68, Headquarters Department of Texas, May 31, 1884.

KOERPER, EGON A., Captain and Assistant Surgeon. Assigned to duty at Fort Keogh, Montana Territory. Par. 1, S. O. 58, Headquarters Department of Dakota, May 27, 1884.

BARNETT, RICHARDS, Captain and Assistant Surgeon. Now on sick leave of absence, is relieved from duty at Columbus Barracks, Ohio, and ordered to report to commanding general, Department of the East, for assignment to duty. Par. 2, S. O. 129, A. G. O., June 4, 1884.

CUNNINGHAM, T. A., Captain and Assistant Surgeon. Ordered to relieve Assistant Surgeon C. B. Byrne, U. S. A., from duty at Fort Lewis, Colorado. Assistant Surgeon Byrne, when so relieved, ordered to proceed to Fort Gibson, Indian Territory, and report to the post commander for duty. Par. 2, S. O. 112, Headquarters Department of the Missouri, June 4, 1884.

BANISTER, J. M., First Lieutenant and Assistant Surgeon. Granted leave of absence for one month and seven days, to commence June 13th. S. O. 22, Headquarters Division of the Atlantic, June 5, 1884.

MC CREERY, GEORGE, First Lieutenant and Assistant Surgeon. Granted leave of absence for two months, with permission to apply to the Adjutant-General of the army for two months' extension. Par. 3, S. O. 56, Headquarters Division of the Missouri, June 5, 1884.

WILSON, GEORGE F., First Lieutenant and Assistant Surgeon. Relieved from temporary duty at Fort Canby, Washington Territory, and ordered to return to his proper station (Fort Walla Walla, Washington Territory). Par. 2, S. O. 70, Headquarters Department of Colorado, May 26, 1884.

OWEN, WILLIAM O., JR., First Lieutenant and Assistant Sur-

geon. Having reported at these headquarters, in compliance with Par. 5, Department Special Orders No. 62, current series, will return to and take station at Fort Stevens, Oregon.

In addition to his duties at Fort Stevens, Assistant Surgeon Owen will perform those of medical officer at Fort Canby, Washington Territory. Par. 1, S. O. 70, Headquarters Department of Colorado, May 26, 1884.

NAVAL INTELLIGENCE.—*Official List of Changes in the Medical Corps of the Navy during the Week ending June 7, 1884:*

MURRAY, J. M., Passed Assistant Surgeon. Detached from U. S. S. Passaic and ordered to U. S. S. Constellation.

MARTIN, W., Passed Assistant Surgeon. Detached from U. S. S. Constellation and ordered to U. S. S. Passaic.

CRAIG, T. C., Passed Assistant Surgeon. Detached from U. S. S. Minnesota and ordered to U. S. S. Vandalia.

DEANE, C. W., Passed Assistant Surgeon. Detached from U. S. S. Vandalia and ordered to U. S. S. Minnesota.

HALL, J. H., Passed Assistant Surgeon. Detached from U. S. S. Minnesota and ordered to Naval Hospital, Brooklyn.

WALES, P. S., Medical Director. To continue present duty until August 1, 1884.

WELLS, H. M., Surgeon. To temporary duty at Naval Laboratory.

MARSTELLER, E. H., Passed Assistant Surgeon. Detached from U. S. S. Vermont and ordered to U. S. S. Monongahela.

SCOTT, H. B., Assistant Surgeon. Commission to date from July 11, 1883.

MEANS, V. C. B., Assistant Surgeon. Commission to date from June 3, 1884.

HESLER, F. A., Assistant Surgeon. Commission to date from June 3, 1884.

SOCIETY MEETINGS FOR THE COMING WEEK.—*Monday, June 16th:* New York County Medical Association; Medico-Chirurgical Society of German Physicians.

Tuesday, June 17th: New York Academy of Medicine (Section in Medicine); Medical Societies of the Counties of Kings and Westchester (annual), N. Y.; Ogdensburgh, N. Y., Medical Association.

Wednesday, June 18th: American Neurological Association (New York—first day); Medical Societies of the Counties of Alleghany (annual) and Tompkins (annual), N. Y.; New Jersey Academy of Medicine.

Thursday, June 19th: American Neurological Association (second day); Roman Medical Society.

Friday, June 20th: American Neurological Association (third day).

Letters to the Editor.

AN UNUSUAL EFFECT OF ERGOT.

38 NORTH DIAMOND STREET, ALLEGHANY, PA., May 27, 1884.

To the Editor of the *New York Medical Journal*:

SIR: The following singular action of ergot may be worth recording: A very healthy woman, aged twenty-five years, had a miscarriage April 7th. The after-hæmorrhage still continuing, on Tuesday, May 20th, I ordered Squibb's fluid extract of ergot, twenty drops three times a day. No effect having been observed, on Saturday, 24th inst., I directed a *teaspoonful* thrice daily. The first spoonful was taken on Saturday evening, and repeated on Sunday morning, noon, and evening. On Sunday morning the patient's forearms and hands, legs and feet, became very red and swollen. She was nervous, restless; her lower

limbs felt sore, tender, very heavy, "as though they weighed a hundred pounds." She arose with difficulty from a chair, and could walk with ease only after the exertion of half an hour. Fleeting pains passed through her shoulders. Whenever she closed her eyes she thought "she saw lightning." There was the sensation of pricking in upper and lower extremities. She was drowsy, and slept nearly all day. She was exceedingly cold. Clothed in her summer wear at first, she resorted on Sunday to winter wear, and slept under winter bed-clothing at night. On Monday morning, the unusual condition having passed away entirely, she took another teaspoonful of ergot, and in less than one hour Sunday's features had all returned. She became again cold, the extremities red and œdematous. She was again very sleepy; indeed, while cutting bread for dinner she fell asleep with the bread-knife in her hand, and was sleeping soundly when her husband came into dinner. I saw her in the afternoon; the drowsiness had disappeared, and all subjective and objective phenomena had passed away. She was like herself again. The metrorrhagia was lessened.

Yours truly,

RICHARD B. FAULKNER, M. D.

RECTAL ETHERIZATION.

NEW YORK, May 23, 1884.

To the Editor of the *New York Medical Journal*:

SIR: In your last issue of this journal you speak of "rectal etherization" as a "therapeutic novelty lately proposed by M. Mollière, of Lyons." Any one reading your editorial would be led to suppose that M. M. was the originator of the so-called novelty. It is therefore that I beg leave to call your attention to the following two facts: 1. This *modus operandi anæsthetica* was devised by Pirogoff. 2. That it was done so shortly after the discovery of the anæsthetic virtue of ether. Ether, as we know, was first used in 1846 by Morton, and it was but one year later that Pirogoff brought forth his method (Pirogoff's "Kriegs-chirurgie," edition 1864, p. 1061). The practical application of this plan was rendered comparatively simple through the introduction of an apparatus constructed by von Bruns not long after (von Bruns's "Chirurgische Heilmittellehre," edition 1873, vol. i, p. 311). "Credit to him to whom credit is due."

Respectfully yours,

S. S.

* * Notwithstanding our correspondent's statements, we still think that rectal etherization is a therapeutic novelty—on the principle that cremation, for instance, although practiced by the ancients, is generally looked upon as a novelty at the present time. As to credit, it seems to us tolerably clear that no New York surgeon will grudge anybody whatever credit may attach to the introduction of rectal etherization.

Proceedings of Societies.

THE MASSACHUSETTS MEDICAL SOCIETY.

One Hundred and Third Annual Meeting, held in Boston, June 10 and 11, 1884.

The President, Dr. ALFRED HOSMER, of Watertown, in the chair.

Tuesday's Proceedings.

THE morning was spent in visits, by invitation, to the Massachusetts General Hospital, the Boston City Hospital, the Lying-in Hospital, the Children's Hospital, and the Boston Dispensary.

METHODS OF INSTRUCTION AND RESEARCH IN PHYSIOLOGY, WITH DEMONSTRATIONS.—At noon the Society assembled at the Harvard Medical School, and Dr. H. P. BOWDITCH, of Boston, gave a general description of the methods of physiological instruction followed in the school, explaining the arrangement of the rooms set apart for that purpose and the appliances for demonstrations. The laboratories were shown, where experiments were in progress under the direction of Dr. Bowditch's assistants. Among many interesting demonstrations, the effect of electrical stimulation of the vaso-motor nerves was shown on an etherized and curarized cat; the same stimulation was shown upon the carotid circulation of a dog; the action of the semi-lunar valves was demonstrated on an ox's heart; ciliary action was beautifully shown in the mucous membrane of the frog; and the effect of temperature on the circulation was illustrated on the same animal.

MODERN METHODS IN ANATOMY, WITH DEMONSTRATIONS.—Dr. THOMAS DWIGHT spoke of the importance of the study of anatomy, and refuted the notion that it was a fixed science in which no further progress was to be made, alluding to recent advances in the topographical anatomy of the viscera, which he illustrated by sections from frozen bodies. He then referred to the statement, made long ago by Dr. Jeffries Wyman, that the bones were constructed after the manner of braces—an opinion that had been elaborated and in part verified by recent research. He next showed a series of fusible-metal preparations, demonstrating the minute ramifications of the vessels in the different organs. After these demonstrations, the members were shown through the rooms of the anatomical department.

THE PLASTER POSTERIOR SPLINT IN THE TREATMENT OF FRACTURES OF THE LEG, WITH ITS PRACTICAL APPLICATION.—The afternoon session, at Huntington Hall, in the Institute of Technology, was opened with a paper on this subject, by Dr. GEORGE W. GAY, of Boston, who gave a demonstration of the measures alluded to in the paper. The desirable features in a leg splint he thought were best embodied in the plaster posterior splint, which had for many years been in constant use in the Boston City Hospital. It was made of sheet wadding, coarse muslin, or crinoline, and plaster of Paris, and was applied as follows: The leg was washed and dried, and enveloped in the wadding, which had been torn into strips about four inches wide, sewn together, and made into rolls like an ordinary bandage. Enough should be used to protect the bony processes and the tendo Achillis from pressure. A single layer of the gauze, large enough to extend from the toes to above the knee, was to be placed beneath the limb, closely wrapped about it, and cut so as to surround it completely, with the exception of a space about an inch wide on the anterior aspect. This piece served as a pattern by which the other layers, six or eight in all, were to be made. The muslin was to be slashed on each side opposite the point of the heel, to allow the foot-piece to be brought to a right angle without forming clumsy folds. Other slashes might be required to make the dressing fit snugly and smoothly, and to prevent wrinkles. Fresh plaster of Paris, mixed with warm water to the consistency of cream, was now to be thoroughly rubbed into each layer of the gauze, and the whole applied to the limb at once, molded closely and carefully to the inequalities, and firmly secured with a common bandage. The fragments were to be held in their proper place until the splint had become sufficiently firm to prevent displacement, which, with good plaster, would not be over fifteen or twenty minutes. In some cases this might be accomplished by means of sand-bags or pillows. In a few hours the outer bandage could be removed and the wadding cut open with scissors. The appliance was then complete, and could be worn with comfort for several weeks.

Particular attention was called to a few points in adjusting

this plaster case. The greatest pains should be taken to hold the fragments in their proper position until the plaster had set; otherwise they might get displaced, when a new bandage would be required, or a deformity would be the result. The foot should be placed at nearly a right angle to the leg, especially if the fracture was at or near the ankle joint. Little padding was required except about the heel and malleoli. Care should be taken that no wrinkles or folds were allowed to press upon the limb. The splint should reach to the metatarso-phalangeal articulation below, and, as a rule, should extend above the knee, particularly in children, to prevent twisting of the fragments in their long axis, or, in other words, to hold the foot in its natural relation to the knee. It should embrace about three-fourths of the circumference of the limb, in order to give the desired support, and retain itself in position. Although especially adapted for simple fracture of the tibia, or of the tibia and fibula, unattended with injury to the soft parts, the splint might also be used for compound fractures, if the soft tissues were not too extensively injured, and if the wounds were so situated that they could be exposed through holes in the splint. Strips of hoop-iron were used in these cases to strengthen the splint.

Contrary to the teaching of some authorities, the reader believed in the frequent examination of broken limbs until the fragments were so closely joined that they could not be displaced easily. Broken ribs and clavicles, though necessarily subjected to constant motion, almost always united well. So did fractures complicated with delirium tremens or excessive restlessness or insubordination, by which the limbs often sustained great violence.

The position of the fragments incased in the apparatus under consideration could frequently be determined by simply sliding the fingers along inside the splint without removing it. But, to examine the parts thoroughly, the case must be sprung open forcibly and the leg carefully lifted out.

The reader wished it to be distinctly understood that this dressing was not adapted to all varieties of fracture of the leg. For example, some cases of Pott's fracture accompanied by marked inversion of the foot, requiring strong pressure to restore it to its proper position and keep it there, could perhaps be better treated by other methods. So, likewise, might cases of oblique fracture of the tibia, with great over-riding of the fragments. Soft parts that had been severely contused should not be subjected to pressure until all danger of ulceration and sloughing had passed. The presence of blebs or blisters, however, did not necessarily preclude the use of this dressing, as they might often be treated through an opening in the plaster.

The reader thought enthusiasm got the better of judgment when patients were allowed to move about on crutches soon after an immovable dressing had been applied to a recent fracture. In cases of Pott's fracture he would not allow the patient to bear his full weight on the foot for months, as displacement and deformity were prone to return.

THE QUESTION OF THE ADMISSION OF WOMEN TO MEMBERSHIP.—At four o'clock an adjourned business meeting was held, in accordance with a vote passed at the last annual meeting, and the question came up as to which body could originate an amendment to the by-laws, the Society or the councilors of the Society. It was decided that either body could take such action, and the amendment to be acted upon at the present time was one that provided for the admission of women to membership. The amendment was finally passed, by a vote of 209 ayes to 123 nays. [The amendment does not become operative until it is confirmed by the councilors. The councilors at their meeting in the evening voted to concur with the Society on the question of the admission of women; so hereafter they will be admitted.]

THE NEW BUILDING OF THE HARVARD MEDICAL SCHOOL was thrown open to the members at five o'clock, and refreshments were served.

Wednesday's Proceedings.

A CASE OF CHYLOUS DEPOSIT IN THE ABDOMEN.—The reports of the secretary and the treasurer having been read and accepted, Dr. FRANKLIN NICKERSON, of Lowell, read an account of the case of a man, fifty-five years old, who was seized January 15, 1877, with violent pain, shooting from the lower part of the spine directly forward to the lower part of the abdomen. A tumor was found which was considered to be a distended bladder. Catheterization gave negative results, but, on aspiration, a quart of milky fluid was removed, giving relief and followed by disappearance of the tumor. An experience like this was repeated on March 21 and October 3, 1877, and on July 28, 1878. From the first aspiration till a year ago he experienced pain in the same situation as above described. During this period there occurred vomiting of chylous fluid at various intervals. Patient had an aversion to milk, and disliked fat. A year ago there was an attack of chylous vomiting, accompanied by loose discharges of a similar character from the bowels. An examination of the aspirated fluid was made. Its general appearance was that of milk. When it stood, a diffuse coagulum formed. It was odorless, and had a mawkish taste. Its specific gravity was 1.018, and its reaction alkaline. Ether extracted from it largely a clear, yellow fluid, from which, on the addition of nitric acid, an albuminous precipitate was thrown down. Under the microscope were seen large quantities of molecular granules, fat globules, occasional crystals of cholesterolin, and granular corpuscles of different sizes, in some of which nuclei were revealed on the addition of acetic acid. A summary of the literature of lacteal and lymphatic effusions was given, but no case exactly parallel throughout had been found.

A comparison of different chemical analyses, the proximity of the tumor to the chylous centers, the suddenness of its appearance, the locality of the pain, and the severe strain upon the abdomen required in the patient's occupation (that of a door-polisher), led to the conclusion that this was a case of discharge of chyle from ruptured lacteals. The absence of any marked prostration or loss of flesh excluded malignant or organic disease. The maintenance of strength for so long a time was attributed to the fact that the loss of chyle was probably not so great as it had been in other cases on record, with which great weakness and emaciation were invariably associated.

THE PITCH OF THE PERCUSSION SOUND.—Dr. LEONARD HUNTRESS, of Lowell, read a paper which showed careful and intelligent study upon the subject. He divided the elements of sound into pitch, quality, intensity, and duration, thus differing from most writers, Seitz being the only one who included duration. Duration differed from pitch in that the latter referred to the number of sound waves which struck the tympanum in a given time, and the former to the length of time the waves continued striking this membrane. The quality of a sound might be so significant as to be of more value in diagnosis than pitch, but *pitch* was of more importance than intensity. Two characteristics always aided in determining the pitch of a sound. A high sound was of shorter duration and of harder tone. A low sound was of longer duration and of softer tone. On two points he desired to dwell: The first was the difference in pitch between the percussion sound of the right infra-clavicular region and that of the left in the healthy thorax. Several years ago he was taught by Dr. Gutmann, of Berlin, who followed Traube in this regard, that the pitch was in most cases higher on the left side. All the instruction he had previously received had been the reverse. So he determined to ascertain what was gen-

erally taught and to make some experiments for himself. Dr. Flint, whose work he had previously studied, was very emphatic in teaching that in the majority of cases the pitch was higher in the right than in the left infra-clavicular region. The reader had made a careful study of the literature of percussion, with the following general result: Most writers made no mention of the matter, and, of the few who compared the two sides, the majority said that both were exactly alike in pitch, intensity, and quality in the infra-clavicular regions. Traube and Gutmann declared that the pitch was generally higher on the left side; Flint, Da Costa, and Seitz, that it was higher on the right.

What should we expect *a priori*? We have not much to base our opinion upon.

The pitch of the percussion sound of the lung depends on the tension of chest-wall and parenchyma, and the volume of the lung being directly as the tension and inversely as the volume.

There is no uniform difference of tension between the right and the left lung. At least, no difference is recognized by medical writers. There is a difference in volume, the right lung being the larger. So we should expect to find the right lung lower pitched. Should the reverse be true, we should conclude that the tension of the right lung was greater than that of the left.

The reader had examined two hundred subjects, all between the ages of twenty and forty, all being in good health, and having symmetrical thoraces.

The result was as follows:

No difference.	72
Pitch slightly higher on the right side.	71
Pitch slightly higher on the left side.	26
Pitch markedly higher on the right side.	23
Pitch markedly higher on the left side.	8
	200

The significance of this result is that, out of two hundred cases, in only seventy-two, or but little more than one third, is the pitch equal on both sides. In one hundred and four cases, a little more than one half, the pitch is higher on the right side than on the left in the infra-clavicular region. In thirty-four cases the reverse is true.

What was the practical bearing of this? A difference in pitch—which meant also a difference in intensity and quality—at the apex of either lung did not necessarily indicate disease. According to these investigations, there is a difference in nearly two thirds of the cases. This is not generally taught. Those who taught that there was any difference represented the pitch as so rarely raised on the left side that its elevation there was considered almost certain proof of disease. Although it was much more significant to find the left lung showing dullness at the apex than the right, yet this was by no means proof of disease.

Dr. Flint in his work on the respiratory organs says that "the pitch of the tympanitic sound is always higher than that of normal vesicular resonance." This discrepancy of statement he considered not because he found that these authorities disagree, but there are so many instances of loose and incorrect writing in medical works that he thought a protest now and then was needed.

The normal vesicular resonance is a good example of non-tympanitic resonance.

The resonance of pulmonary cavities under certain conditions and that of the stomach and intestines, when not too tensely inflated, are good examples of the tympanitic sound.

The tympanitic sound is a clearer, more ringing, and more musical sound, the sound waves striking upon the tympanum at regular periods. The non-tympanitic sound is less a musical sound, and here the waves strike the tympanum irregularly.

Percuss a freshly removed sheep's lung without inflation, and you obtain a clear, ringing, musical, tympanitic sound of low pitch. Inflate the lung to the degree of tension maintained in life, and the sound is less a musical tone and non-tympanitic. Here pitch is raised. Or take a pig's bladder just barely filled with air with no stretching of the membrane, and on percussion the sound is tympanitic. Now inflate forcibly until the walls are tense, and the sound is non-tympanitic.

According to Skoda, the tension of the membranes was the chief, if not the only, necessary condition of non-tympanicity, and *vice versa*.

The explanation was, that when the membrane is tense it is capable of vibrating, and its vibrations mingle with the vibrating air within, and, not being in harmony with them, destroys their regular periodicity and then the tympanicity.

These conditions which favor retraction of the lung tissue often gave rise to tympanitic sounds, just as the sheep's lung, when allowed to assume its natural, uninflated volume, gives tympanitic sound.

To illustrate one pathological condition under this head. In moderate pleuritic exudation the lung above the level of the fluid shrinks in volume, and, when this retraction reaches a certain point, the percussion sound is tympanitic. Here the pitch is lowered as the tension is diminished.

If all cases where the sound is tympanitic could be thus disposed of, Dr. Loomis would be justified in his broad statement. Without attempting to classify all the conditions which give rise to a tympanitic sound, he mentioned a class of cases very different from that just discussed, to wit, pulmonary cavities.

A cavity is either completely occluded by its walls, or it communicates with adjoining lung tissue. If the cavity is completely occluded, the wall must be elastic, and must not be stretched too tensely in order to produce tympanitic sound. Here the pitch of this tympanitic sound depends on the tension of the walls and the volume, being directly as to the tension and inversely as to the volume. If the cavity communicates by an opening with the adjoining tissue, sound may be tympanitic with either elastic or non-elastic walls. If the walls are non-elastic, pitch depends upon volume of cavity and on the diameter of the opening of communication, being inversely as the volume and directly as the diameter of the opening. If the walls are elastic, pitch depends on these two factors in just the same way, also on their tension being, of course, in direct ratio with the tension. There is also the general law that pitch of cavities depends *ceteris paribus* on the elasticity of the wall being in inverse proportion to such elasticity. If a cavity is sufficiently long and narrow—i. e., if the length of the long diameter sufficiently exceeds that of the short diameter, so as to give it the form of a tube—the pitch does not depend upon the volume, but upon the length of the air-vibrating column being in inverse ratio with the length of the column.

It is true that the tympanitic sound of the abdomen is higher pitched than normal vesicular resonance. This is not because it is tympanitic. It is rather in spite of that fact. We have seen that, in tympanicity from lung retraction, this pitch is lowered. We have also seen that, in the case of the tympanitic sound of pulmonary cavities, the pitch is sometimes high and sometimes low, according to the elasticity and the tension of the walls, the diameter of the opening of communication, the volume of the cavity, or the length of the air-vibrating column.

Perhaps Dr. Flint arrives at his conclusion by simply comparing the sounds of a tympanitic abdomen with the normal vesicular resonance; and Dr. Loomis may arrive at his by thinking, with Skoda, that the sole cause of tympanicity is relaxation and decrease of tension of surrounding wall.

(To be concluded.)

NEW YORK ACADEMY OF MEDICINE.

Meeting of June 5, 1884.

The President, FORDYCE BARKER, M. D., LL. D., in the chair.

(Continued from page 641.)

THE LATE DR. WILLIAM H. HUBBARD.—Dr. F. A. BURRELL offered the following resolution, which was carried unanimously:

Resolved, That the sympathies of the Fellows of the Academy be expressed to our esteemed and well-tried associate, Dr. Samuel T. Hubbard, in view of the great sorrow he has experienced in the loss of his son, Dr. William Hustace Hubbard, who has been taken away on the very threshold of a promising career.

A PLEA FOR MORE HEROIC SURGICAL INTERFERENCE IN AFFECTIONS OF THE BRAIN.—Dr. R. W. AMIDON read a paper with this title, in which he sustained his plea by facts based upon a review of the statistics of injuries to the skull and brain. Walsham had collected over six hundred cases in which the trephine had been employed. Over four hundred of the patients died, but an analysis, according to Walsham, showed that only ten and six tenths per cent. died from the operation itself. Dr. Amidon thought that this percentage was greater than a strict analysis of the cases would justify. He had recently collected one hundred cases in which trephining or similar operations had been done since 1879, the cases being taken without special selection. His conclusions with regard to the cause of death in the cases in which it took place, whether due to the operation or not, were based upon a study of the pathological conditions, the prominent symptoms before and after the operation, the kind of operation, the dressing and subsequent treatment of the wound, and the final result. From these data it had been possible to arrive at pretty conclusive evidence as to the mortality of the operation *per se* as looked at in the light of modern surgery. Of the hundred patients, twenty-six died, of whom twenty-three had at the time of the operation symptoms endangering life, thus leaving only three cases in which the fatal issue could even be remotely traced to the operation.

It would seem that opening the dura mater had led to a fatal issue in a little over thirty-nine per cent., but, if it were remembered that this was accompanied in most cases by laceration of the brain, hæmorrhage, and the introduction of a foreign body in exploration, it would be found that the mere opening of this membrane was not responsible for death in thirty-nine per cent. of the cases. On the contrary, an analysis showed that it was the cause of death in only a little over seven per cent. The author then read the history of only one of a number of cases going to show the toleration and reparative power of the brain after extensive injury, and, among others bearing on this point, referred briefly to a case of gunshot wound of the brain under the care of Dr. Fluhrer, who boldly made a counter-opening, probed for and removed the ball, with complete recovery of the patient. He then briefly reviewed the data regarding cranial and cerebral topography, by which alone cerebral surgery could accomplish brilliant results. Neurologists were perfectly sure that there were certain regions of the brain which, when irritated, compressed, or destroyed, would give rise to perfectly unmistakable symptoms. Recapitulating, he said: "We have in trephining an operation proving fatal in only three per cent. of published cases; the operation of opening the dura mater fatal in only seven and six tenths per cent.; we have in the brain an organ tolerant of injury, and ready to take on reparative process; we possess knowledge, enabling us to tell when certain parts of the brain are diseased, and we have anatomical data enabling us to pierce the cranium to reach those parts."

With regard to the operation, he thought it could be better performed with the dental engine than with the trephine. The principal advantages of the engine were that with it one could cut away as much or as little bone as he pleased, and make the opening of any shape desired. It was specially useful in breaking down the edge of over-riding bone, to allow of the elevation of depressed fragments. The operation should always be done carefully, and we should try to procure only proximal coaptation of the flaps; we should provide for the freest possible drainage, and use cold antiseptic dressings without much compression. He said without much compression, because in one case the operation produced very serious results, which, however, were only temporary. Enjoin the greatest quiet, in a posture to facilitate drainage. Keep up the appetite, and a slightly loose condition of the bowels. In case of a rise of arterial tension and temperature, give *jaborandi* or *aconite* to the production of their physiological effect. Quinine and alcohol should be given only in tonic doses. An anodyne was often indicated, but opium or any of its preparations should never be given. To relieve pain, quiet delirium, or induce sleep, use hydrate of chloral in small and frequently repeated doses—ten to fifteen grains every fifteen or twenty minutes until its effects were produced. Quinine and alcohol in large, and opium in any, doses would aggravate intra-cranial inflammation when present, and he thought might excite it. These suggestions applied equally well, or with still greater force, to cases in which the dura mater or the brain was accidentally or intentionally invaded.

As to the indications for opening the skull, he mentioned injury of the external vault, provided there were marked cerebral symptoms; compound fracture of the skull, whether there was visible depression or not, or cerebral symptoms or not; and cases in which after the lapse of months, or years even, unmistakable cerebral symptoms following injury of the head. In addition to opening the skull, the dura mater should be opened in all cases in which exploration with the hypodermic needle disclosed products of purulent inflammation or a great deal of liquid blood, and in all cases in which serious superficial lesion of the brain was suspected and could not be otherwise proved. In addition to the bone and dura mater, the brain should be explored delicately with the probe in all penetrating wounds of its substance—punctured, lacerated, or gunshot. Its mass should be invaded, even when superficially intact, by a fine, blunt exploring needle when the presence of foreign bodies or of hidden collections of pus was suspected, and either extraction or evacuation should be made with the proper instrument. Finally, he would state theoretically that a neoplasm of the brain which had resisted medical treatment, continuing to grow and to threaten life, should be excised, for the reasons that it would usually be found to be single, there were seldom secondary deposits, it was usually surrounded by an inflammatory zone of demarcation, and always killed by pressure.

Dr. J. P. GARRISH thought the subject under consideration a very important one, and, to encourage the use of the trephine in properly selected cases, he briefly referred to his experience. The first case was that of an epileptic patient, whose attacks dated back five years to the receipt of an injury on the head. He had undergone medicinal treatment at the hands of various physicians. Recognizing a depression in the skull, Dr. Garrish trephined, removed a large piece of the skull, lifted a depressed portion of bone, and the man was completely and permanently cured from the moment of the operation. He had now done the operation in cases of epilepsy five times, and in every instance the patients never had another attack. At the battle of Antietam he found a soldier in the corner of a barn, covered up by straw, who had lain there three days without having been noticed. He had been wounded in the head and was com-

pletely unconscious. Dr. Garrish trephined him, and immediately the patient returned to consciousness, and recovered.

Dr. M. J. ROBERTS described an electrical trephine.

Dr. H. D. NOYES spoke of a case in which he opened the skull a number of years ago, that of a patient who had a fistulous tract in the frontal bone which occasionally discharged matter. The patient suffered from great stupor, and the antecedent history pointed to an abscess; there were also three or four fistulous openings near the right orbit. There had been convulsions, and here he would ask whether convulsions did not have a bearing upon the question of the presence of meningeal inflammation. He trephined above the right eye, punctured the dura mater, and let out about three drachms of pus; the patient regained sensibility, and finally recovered completely. Dr. Detmold had even a good while before this plunged a bistoury deep into a brain and relieved an abscess, so that it had been in the minds of surgeons in this country for a long time to perform such operations, but they had been waiting for more definite knowledge regarding cerebral topography. With regard to his case mentioned by the author, he would like to know whether the administration of alcoholics and quinine, with a view to sustaining the patient's energies and keeping down a dangerous rise of temperature, would militate against the chances of the patient's recovery. He thought the question one which really deserved consideration. In the case referred to, it was true that the patient was doing well at the time he was asked to interfere and correct the deformity, and it was probable he might have continued to do well for some time, but he believed the time would have come when it would be necessary to remove the piece of iron in order to preserve life, and, in his opinion, it was quite proper to undertake its removal so soon as the real nature of the wound had been ascertained, and not to wait until symptoms developed demanding its removal, as the chances of recovery then would probably be diminished.

Dr. L. PUTZEL had seen cases post mortem at Bellevue Hospital in which the condition of the intra-cranial contents was such that one might well suppose the patient would have stood another chance of life had trephining been performed, all other methods of treatment having failed and the patient having been left to die. With regard to the statistics given by Dr. Amidon, he was of the opinion that favorable and not unfavorable cases were likely to be put on record, and thus there would be a better showing for surgical interference than the facts warranted. He thought Dr. Noyes had struck the key-note to the whole question when he spoke of localization. Dr. Putzel thought we did know very much positively with regard to cerebral localization. There was no doubt that we had located the psychomotor centers, and we knew from cerebral topography where they were situated, but we might not be able to tell from the symptoms what part was affected. We might observe, for example, symptoms pointing to a particular surface lesion, but, on operating, or at the autopsy, we might find an internal abscess giving rise to those particular symptoms by cutting across some of the motor fibers before they reached the cortex. There were other cases in which the symptoms did not seem to coincide at all with our present notions of what they ought to be. He gave an illustrative case. We knew only positively with regard to the motor centers. He agreed with Dr. Noyes, that where there was a fistulous opening communicating with the outside it was perfectly proper to probe and try to find out the real condition of affairs. But it seemed to him that, before it became justifiable to make a cutting operation into the brain, our means of diagnosis should be further advanced. With regard to the question raised by Dr. Noyes, he did not think it was positively decided that it was improper to give alcohol and quinine in the condition mentioned. If there were any danger of the patient's

dying of heart failure, the use of alcohol was indicated. As to giving hydrate of chloral every ten or fifteen minutes, in some cases it might require an hour for the drug to produce its effect, and, given in this manner, too much might be administered before its effects became apparent.

Dr. AMIDON agreed with Dr. Noyes and Dr. Putzel that we did not know definitely the effects of quinine in these cases. But in a patient suffering from galloping consumption he gave from forty to fifty grains of quinine a day, and the girl suddenly had marked rise of temperature, chills, very severe frontal headache, ptosis on the left side, external strabismus of the same eye, and paralysis of the lower facial muscles of the left side, and was delirious for three days. The quinine was stopped, iodide of potassium was given in large doses, and she recovered, but afterward died of the lung affection. At the autopsy the only lesion in the brain was simply a little opacity of the pia mater at the base of the brain, and it had been his impression that there had been slight basilar meningitis, the result of the administration of quinine, from which she entirely recovered. He thought that Dr. Noyes was perfectly justified in the treatment adopted in his case. He thought Dr. Putzel had not understood his remarks about cerebral localization; otherwise he would have found them more nearly in accord with his own views than he had supposed.

THE PROPOSED NEW PARKS.—Dr. F. A. CASTLE quoted the arguments of the "New York Medical Journal" of May 31st as to the necessity for more park area in New York, and offered the following resolutions, which were unanimously adopted:

Resolved, That it is the sense of this meeting that the plan sanctioned by the Legislature should meet with the approval of his excellency, Governor Cleveland.

Resolved, That a copy of these resolutions, properly authenticated, be forwarded to Governor Cleveland.

The Academy adjourned, to meet the first Thursday in October.

NEW YORK PATHOLOGICAL SOCIETY.

Meeting of May 28, 1884.

The President, Dr. GEORGE F. SHREAY, in the chair.

SALPINGO-OÖPHORECTOMY.—Dr. M. PUTNAM JACOBI presented the ovaries and oviducts that had been removed by Dr. Elizabeth M. Cushier from an unmarried lady, now thirty-five years old, who had suffered severely with dysmenorrhœa since the age of twenty, although no particular attention had been paid to it until about a year before she consulted Dr. Jacobi, who had found the uterus sharply retroflexed, its cavity somewhat enlarged, and the endometrium exquisitely tender and hyperæmic. The right ovary was prolapsed. On the left side the ovary could not be felt, but there was a soft mass, unlike the exudate of cellulitis, and very sensitive. Dragging the cervix toward the right side always caused very sharp pain in the left side of the pelvis. At times the left ovary could be felt behind the cervix. Besides dysmenorrhœa, there was pain for about a week before each menstrual flow, increasing in intensity until the flow was established. Sometimes, too, there was very sharp pain for a few days after the flow, like a violent neuralgia; and in the intervals there was also constant pain, although less severe, in the left ilio-inguinal region, which frequently extended down the limb.

It was difficult to keep the uterus in position, although the fundus was not adherent, but because of shortening of the utero-vesical folds, which drew the cervix well up under the pubes. This was partly overcome by stretching, and for several weeks, the uterus being kept perfectly in place, the symptoms of perimetritic inflammation disappeared, and yet the symptoms largely

remained as before. For four months the patient was kept in bed, and cotton packing was introduced with a view of pushing up the prolapsed ovary and relieving pressure upon the vessels. After this treatment, together with massage, she was much improved, and for five or six months had no pain during menstruation. Then the pain began to return, and reached a degree demanding the operation. About once in six months while under observation she was seized with a colic of very great intensity, like that of nephritic or biliary colic, which continued for about two hours, and after this there escaped from the uterus a small mass of cheese-like matter. This was supposed to be inspissated mucus which had collected in the uterine end of the Fallopian tube. The operation for the removal of the ovaries and tubes was performed five days ago, under the use of the bichloride solution. The temperature since the operation had not risen above 101° F., and the patient was now considered out of danger. The operation was done eight days after the menstrual period, and pains had been taken to count the number of Graafian follicles. The extraordinary conclusion had lately been drawn, from the frequency with which an unusual number of mature follicles had been found in ovaries removed in Battey's operation, that there was no special relation as to time between menstruation and the ripening of a Graafian follicle. The cases being those of dysmenorrhœa and menorrhagia, we might suppose that there would be an abnormal development of the Graafian follicles. The specimens presented seemed to support this view. The left ovary was turned over, and on its dependent surface was a cyst with which evidently the finger had come in contact and caused acute pain during examinations. The other ovary was in a somewhat similar condition, but the cyst was not quite so large. Dr. Jacobi believed that physicians commonly had an indefinite idea as to the manner in which the ovaries became prolapsed; she thought the condition could only take place by the organ turning over on itself. The uterine extremity of the tubes contained what appeared to be inspissated mucus, a point of interest with relation to the periodic attacks of greatest pain and the discharge of cheese-like masses.

CHRONIC PERITONITIS.—Dr. F. FERGUSON presented specimens showing general chronic peritonitis, with extensive and very firm adhesions. He showed also a specimen illustrating injury of the vermiform appendix, and one of large tuberculous ulcers of the large intestine. A short time ago he had seen the statement that ulceration of the large intestine in connection with tuberculosis was very rare.

Dr. W. M. CARPENTER said, with regard to the specimen of chronic peritonitis, that he was reminded of a monograph by Viorondt entitled "Chronic Exudative Peritonitis," in which the author gave the history of several cases, in some of which the patients recovered and lived for several years, and others finally died of an affection directly or indirectly dependent upon the chronic exudative peritonitis. The appearances described were very much like those presented by the intestines shown by Dr. Ferguson—general agglutination of all the coils of intestine with each other, more or less thickening, but not necessarily any adhesions to the abdominal wall. Ascites was prominent at some period in the history. While reading the monograph he was reminded of two or three cases which he had seen, and in which there had occurred typhoid fever followed by symptoms of subacute peritonitis. There was marked ascites; after a time these symptoms subsided under treatment, and two of the patients ultimately recovered, and lived a number of years. The condition was not traceable to the ordinary causes of peritonitis, nor was there any history of tuberculosis. One of the patients lived for ten or twelve years after being under his care for this condition. Another, a man somewhat advanced in years, lived for four or five years, and ultimately died of cancer which mani-

fested itself upon the lip. He had not seen this group of cases well described before reading the monograph in question, and he believed the case related by Dr. Ferguson belonged to that class. Vierordt also spoke of ulceration of the intestines as one of the causes of chronic exudative peritonitis, a condition already mentioned by Dr. Ferguson as present in his specimen.

BUFFALO MEDICAL AND SURGICAL ASSOCIATION.

Meeting of June 3, 1884.

The President, Dr. F. W. BARTLETT, in the chair.

PARALDEHYDE.—Dr. JUDSON B. ANDREWS, superintendent of the Buffalo State Insane Asylum, read an interesting paper on this new sleep-producing remedy. After briefly reviewing the experience of its Italian introducers, and that of the Americans, Dana, Wilson, and Uhler, with the new hypnotic, he proceeded to give an account of his own trials. To paraldehyde had been ascribed numerous virtues by the foregoing writers. It had been stated that it possessed all the good qualities of chloral, without its dangers; that it did not produce the initial cerebral excitement so common to soporific agents; that no ill effects, such as nausea, depression, or headache, had followed its free administration; that it antagonized strychnine; and that it was antiseptic.

The reader had procured some paraldehyde in September last, at an expense of \$19 a pound. He first experimented upon himself, and found that two-drachm doses put him into a light slumber, lasting but a short time, from which he was easily aroused, and that it was followed by no ill effects. The sphygmograph was used in these experiments. The pulse generally fell and arterial tension was reduced. The peculiar penetrating taste and odor of the breath continued some hours. He then tried two-drachm doses on five other persons, three of whom experienced no hypnotic effect, one was slightly sleepy, and the other slumbered soundly. After this he made use of doses of three drachms. In a case of inebriety this dose raised the pulse in thirty minutes from 88 to 104, causing drowsiness, flushing of the face, and reduced arterial tension, and, after one hour, led to profound sleep until morning. A three-drachm dose having been given to an attendant, sleep followed in thirty minutes and lasted all night; the pulse fell from 88 to 76; and in the morning the man said he felt as if he had been drinking. In none of these cases was there any change in the number or character of the respirations. An effort was made to disguise the pungent taste of the drug with elixir of valerianate of ammonium and syrup of ginger, but without avail. Cold water was subsequently used, as in administering chloral. The reader then reported in detail the effects of paraldehyde in ten cases at the asylum: one of chronic melancholia, two of recent melancholia, four of chronic mania, two of paresis, and one of epilepsy with addiction to opium. The doses ranged from one to three drachms, and were alternated with other hypnotics, in order that their effects might not be misinterpreted. Paraldehyde was given in each case long enough to enable him to judge of its merits. In five of these the results were satisfactory, sleep being produced which might fairly be attributed to the paraldehyde. In five no benefit was experienced.

Doses of three drachms had an effect like that of a stimulant in narcotic doses. Smaller doses, if they produced any effect at all, gave rise to pleasant and natural sleep. It was less rapid in its action than chloral, requiring from thirty to forty-five minutes. There was no initiatory excitement. The respirations were not changed. There was no constant effect on the pulse. It occasionally produced nausea, and the taste was decidedly unpleasant and persistent. It had, in his opinion, no

quality which made it superior or even equal to other hypnotic remedies now in constant use. Its bad taste, the difficulty in disguising it, the large amount of water needed to dilute it, and the fact that it did not supply any demand not already met by other remedies, would, in his opinion, restrict, if not altogether prevent, its general use in either private or hospital practice. He exhibited sphygmographic tracings from many of the cases, made before and after administering paraldehyde. He stated that the price had now fallen to \$7 a pound.

Dr. COAKLEY asked if it would be beneficial in angina pectoris.

Dr. ANDREWS thought it would be of no service, but he had not tested it for its anodyne effect.

Dr. STRONG wished to know if paraldehyde would not be influential in the control of delirium tremens.

Dr. ANDREWS answered that he had had thus far no experience in its use in that disorder.

Dr. CROVYN spoke of the aldehydes as having been long well known to the profession, but seldom used in practice. He thought Dr. Andrews's paper would prevent many from making haphazard use of paraldehyde, and assist greatly in fixing the dose, a difficulty heretofore existing.

Dr. ROCHESTER had tried paraldehyde in one case with total failure to produce a hypnotic effect. In this case chloral gave perfect satisfaction. He thought it better to test the soporific properties of new remedies in asylums than in private practice, because in the former we might observe different results on account of cerebral disorders. For instance, hyoscyamine—a remedy described so glowingly by asylum authorities—had proved in his own practice a most dangerous hypnotic. An agent might be very appropriate for the brain of an insane person, but productive of vastly different results in an individual with a healthy cerebrum. He asked Dr. Andrews for his opinion with regard to Florida dogwood.

Dr. HARTWIG had read of one hospital where two hundred pounds of paraldehyde had been used. He mentioned the new hypnotic and anæsthetic, tannate of cannabine, just introduced in Germany. He had tried five grains without effect.

Dr. ANDREWS said he had hesitated to record his experience with paraldehyde because he had used so small an amount of it, but his cases had presented such uniform results that he felt he ought to report them. He had used one pound. He did not know of a safer remedy than chloral, of which he had used several hundred pounds without ever having observed bad effects. In the early days of its manufacture it was no doubt impure, but its quality had gradually become more perfect.

In answer to Dr. Rochester, he would say that he had experimented with Jamaica dogwood in the same manner as with paraldehyde. He had found dogwood not a good hypnotic, and of very little value. It had a slight soothing effect, and he would place it about on a par with valerian. It had not the extraordinary qualities ascribed to it. He had used three-drachm doses of a preparation labeled, "Dose, fifteen drops."

With regard to hyoscyamine, he was sorry to hear Dr. Rochester speak so ill of it. He had seen bad but not dangerous effects from it. He had witnessed patients, after a dose, fall as if in apoplexy, with congestion of the face and a rise in temperature, sometimes even with symptoms like coma, but such effects had passed off. He used it not largely, but nevertheless continually, at the asylum, always by the mouth, in doses of $\frac{1}{4}$ to $\frac{1}{2}$ of a grain dissolved in water, and never hypodermically. Merck's uncrystallized hyoscyamine was the best. The ordinary dose was $\frac{1}{4}$ of a grain. In English asylums as much as one grain was occasionally used. The pulse sometimes ran up to between 120 and 140 after the remedy was given.

DEATH OF DR. SANFORD B. HUNT.—Dr. ROCHESTER an-

nounced officially the death of Dr. Hunt, the physician and journalist. He came to Buffalo in 1853, and was associated with Dr. Austin Flint in the editorship of the "Buffalo Medical and Surgical Journal." He was for several years professor of anatomy in the University of Buffalo, a position he filled admirably. But as a medical journalist we had never had his superior. He was for several years the secretary of the Buffalo Medical and Surgical Association, and his reports were models of excellence; indeed, so facile was his pen that many gentlemen scarcely recognized their own remarks. He finally left the ranks of the profession to become a regular journalist of the daily press, yet not before he had shown marked ability and skill as a surgeon in the army during the war. After an absence of twenty years, Buffalo was still so dear to him that he desired to be buried here. Dr. Rochester moved that our regret at his loss to us and to the profession be placed upon the minutes of this meeting as a tribute to his memory and a mark of respect to his family. Carried.

Dr. WYCKOFF, Dr. GAY, and Dr. STRONG severally eulogized his intellect and talents, and recalled pleasant associations with him of a score of years ago.

ANEURYSM OF THE AORTA.—Dr. HAYD presented an aneurysm of the aorta removed at an autopsy this morning. It was interesting from the fact that the young man was a diver, and was accustomed to remain under water ten hours or more with a bell, causing a great strain upon his system. This led undoubtedly to a chronic endarteritis deformans, with dilatation and sacculation of the first part of the aortic arch. The sac contained several stratified deposits of fibrin. There were a few *végétations globuleuses* upon the aortic and mitral valves. The aortic valve was thickened.

GALL-STONES IN THE LIVER.—Dr. HARTWIG reported a case observed by him for some months, in which he had made a diagnosis of hepatic abscess, while other physicians had called it hepatitis. The patient, who had been suffering for two years, had little or no pain over the liver, but there was enlargement of the organ. He introduced a hypodermic needle into the liver in two places without finding pus. On post-mortem examination, there were found several thousand small abscesses in the liver, each containing a calculus. The gall-bladder also was completely filled with gall-stones. Some suppuration had taken place in one of the wounds made by the needle, and he believed puncture of the liver with a needle to be dangerous, especially on account of the great vessels at the hilum.

Dr. CRONYN observed that piercing an artery with a needle was not at all hazardous, for the tissue about the puncture contracted at once.

Dr. HARTWIG said he was loth to believe this unless it was proved by actual experiment upon animals.

THE PROPOSED DIVISION OF THE ASSOCIATION INTO SECTIONS.—Dr. COAKLEY, chairman of the committee appointed at the last meeting to report upon this subject, stated that a circular had been sent to each of the hundred members of the association, requesting the enrollment of his name in one of the four proposed sections, viz., medicine, surgery, obstetrics, and pharmacy. He had received only fifteen responses, and several of the writers were opposed to the division.

In a short discussion which followed the remarks of the chairman, Dr. TREMAINE, Dr. CRONYN, and Dr. HARTWIG expressed themselves against the change, believing the association was as yet too small, the specialists in it too few, and, further, that it was wisest to make ourselves specialists in general medicine.

A motion of Dr. ANDREWS that the committee be continued was carried and the meeting adjourned.

FREDERICK PETERSON, M. D., Secretary.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

Meeting of May 21, 1884.

THE BACILLUS THEORY OF TUBERCULOSIS.—[After the reading of an interesting paper on "The Type of Typhoid Fever Prevalent Last Winter, with Pathological Specimens," by Dr. George W. Vogler; and a "Warning to Medical Practitioners in regard to the Use of Jequrity," by Dr. M. Landesberg—both of which we are obliged to omit on account of lack of space—the society proceeded to the discussion of Dr. Formad's paper on "Tuberculosis," as follows:]

Dr. SHAKESPEARE regretted his inability to be present to open the discussion in accordance with the request of the President, and thanked the society for this opportunity of expressing his views. He had been much interested by the opinions and by the review of the status of the tuberculosis question presented by the author. There were, however, very many points assumed as demonstrated, and positive statements advanced in the elaboration of Dr. Formad's paper, which Dr. Shakespeare believed to be without sufficient foundation. But he would not, at this time, enter into a general criticism. He preferred to await the detailed observations which the author promised should be forthcoming in support of the many statements and conclusions he had thought proper to announce in advance. He intended to limit his remarks to-night to some differences between himself and the author as to statements made by the latter concerning a recent visit to Koch's laboratory. Dr. Shakespeare also had been in Berlin last summer, and had then enjoyed the privilege for about a month of working under Koch and his assistants during six or seven hours daily.

1st. The author had declared, in terms far less equivocal than those printed, that Koch's policy was to hinder or prevent strangers who visited the *Gesundheitsamt* from retracing his now famous experiments upon tuberculosis, and stated that no one had ever been permitted to inquire into the infectiousness or parasitic nature of tuberculosis, save one man.

2d. The author had further announced that Koch had so far modified his views that he now admitted that neither the form, size, and aspect of the tubercle bacillus, nor its want of individual motion, nor its peculiar behavior toward staining fluids, distinguished it from many other bacilli.

Dr. Shakespeare regarded these statements as misrepresentations of Koch's animus, as well as of his present opinions. He felt impelled to thus publicly express himself, because perhaps every member present had known of his late visit to the *Kaiserlichen Gesundheitsamt*. To be silent under these circumstances would constitute a tacit assent to these declarations—a false position in which he was unwilling to be placed. Moreover, the grave importance of this whole question; the presumed desire of this learned society to be possessed of all the evidence bearing upon every phase of it; justice to the fairness, honesty, and consistency of the distinguished author of the bacillus theory of tuberculosis, whether it were true or false, forced him to express now his dissent from the foregoing declarations of his friend.

Previous to the announcement of the discovery of the "tubercle bacillus" he had been most favorably impressed by the exactness and completeness of Koch's labors in the final establishment of the parasitic nature of anthrax (French, *charbon*; German, *Milzbrand*; English, splenic fever), as also by the evident caution and reliability of that investigator. This had prepared him to begin the examination of the grounds of Koch's startling claims regarding the nature of tuberculosis with no small degree of respect for their author. At that time he had no definite views concerning the cause, infectiousness, or con-

tagiousness of tuberculosis. Certainly he did not commence this examination with a mind wholly preoccupied by a theory of his own which he thought to be in conflict with that of Koch.

He had not gone to Berlin for the purpose of discovering there the truth or falsity of the claims for the "tubercle bacillus." On the contrary, recognizing the growing importance of research among the various forms of bacteria as possible causes or modifiers of pathological processes, and having personally experienced much trouble in prosecuting such studies while following described methods, and, through his intimate relations with the University of Pennsylvania, having known of similar difficulties in the pathological laboratory of that school of medicine, he had at length determined to obtain, if possible, ocular demonstration of Koch's classic methods of isolation, culture, and study of minute organisms, and had become one of "the pilgrims" to that Mecca toward which Dr. Formad himself had directed his steps only a few weeks before.

Arrived in Berlin, he had been most cordially welcomed at the *Gesundheitsamt* by Dr. Koch and his corps of accomplished co-laborers, and every possible facility for furthering the object of his visit had been most willingly and courteously tendered during the whole of his stay, though doubtless at the cost of much inconvenience, for, besides work upon important investigations, active preparations for the departure of the cholera expedition to Egypt were then in progress. He could say that he had never spent a month with more pleasure or profit. While it had not been his desire to give especial attention to the "*Bacillus tuberculosis*" more than to the *Bacillus anthracis* and to other bacteria, yet, so far as his wish extended, and the limited time at his disposal served, in his practical work the "*Bacillus tuberculosis*" was not neglected.

He felt impelled to say, in the most emphatic and unmistakable language which he could use, that he himself was not only readily permitted to go as far as he wished in the investigation of the tubercle bacillus, but, furthermore, on no single occasion did he meet with any hindrance whatever, or perceive the slightest indication of a desire on the part of Koch to prevent the retracing of his experiments upon that subject. He had heard of no one having met such a difficulty there other than Dr. Formad. The only person who, previous to the presentation of the paper under discussion, had to his knowledge published an account of personal work done upon tuberculosis in Koch's laboratory was Watson Cheyne, of England, whose report amply testified to Koch's willingness to have his experiments examined. Dr. Formad, in his communication as printed, excepted this work of Watson Cheyne, perhaps wisely, for he several times quoted it for other purposes.

If Dr. Formad, during the three or four days of his attendance at Koch's laboratory, did not experience an enthusiastic reception, and, as he intimated, was not permitted to experiment upon the pathogenic qualities of the tubercle bacillus, he might far more reasonably have attributed this coldness to an irritation naturally produced by his published remarks in which Koch had been accused of unscientific work, and the insinuation been offered that the researches made at the Imperial Health Office had been unduly influenced by Kaiser Wilhelm, than have assumed from his reception that Koch habitually objected to have any one look into the genuineness and reliability of his work upon tuberculosis. Indeed, the simple fact of his admission at all, under the circumstances, could fairly have been regarded as evidence of Koch's willingness to open his laboratory even to an opponent whom he regarded as unfair. The *Gesundheitsamt* was a department of the German Government. Koch and his chief assistants were officers of the German army or navy. They were all intensely loyal to their Emperor.

They believed that Dr. Formad had purposely and unjustifiably stepped outside the proper sphere of a purely scientific communication to publish a reflection insulting to them and their Kaiser.

Before dismissing this indirect attack upon the reliability of Koch's published observations upon tuberculosis, Dr. Shakespeare took this opportunity to say that his personal observation of Koch, as well as a careful examination of his publications, had led him to the conviction that the whole medical fraternity did not possess a more painstaking, capable, cautious, thoroughly honest and reliable investigator of the causes of disease than the distinguished discoverer of the tubercle bacillus. He would speak in similar terms of those of the corps of official co-laborers at the *Gesundheitsamt* with whom he had come in contact sufficiently often to form an opinion.

The second statement above mentioned, namely, that Koch had now essentially modified his views concerning the characteristics of the tubercle bacillus, was next examined. Dr. Shakespeare could only say that Dr. Formad's extraordinary announcement was the first and the only information upon this point which he had received. Certainly he had heard nothing and seen nothing while at the *Gesundheitsamt* which could in any manner confirm such a statement. It is true that, while at Berlin, the author had related to him his interview with Koch, and had said that the latter had been far less dogmatic than he had expected, mentioning among other things a little friendly controversy concerning their opposite views in which Koch had seemed quite willing to admit the possibility that under favorable circumstances the tubercle bacillus might develop a flagellum at its extremity, and thus become endowed with individual motion (Dr. Formad had professed to have seen this motion), and had appeared quite willing to admit also the possibility that in the course of time it might be discovered that other bacteria would react toward staining fluids in a manner identical to the reaction of the tubercle bacillus. But an admission that certain things *might be possible* and a statement, based upon present knowledge and experience, that they did exist, or even were probable, were quite different matters. During Dr. Shakespeare's work upon the tubercle bacillus in Koch's laboratory, which was after the termination of the short visit of Dr. Formad, he was taught to differentiate the tubercle bacillus from all other bacilli by means of its characteristic reaction, now well known, toward certain staining agents, no less than by its peculiar size and shape, as seen under high magnifying powers (Zeiss's $\frac{1}{2}$ was generally used for this purpose). The statement that the author of the bacillus theory of tuberculosis had practically withdrawn his claim that there was something characteristic in the staining of the tubercle bacillus and in its morphology which distinguished it from other bacilli was the more astonishing and incredible because of the fact that, besides the existence of overwhelming testimony from all quarters of the globe in confirmation of this original claim, even Dr. Formad, however persistently in print he might assail this claim of peculiarity, was himself in the habit of differentiating this minute organism from all other known bacilli for purposes of diagnosis and of demonstration to his pupils by means of this self-same characteristic coloring and morphology.

Although it had not originally been his intention to discuss them this evening, Dr. Shakespeare briefly considered Dr. Formad's claims of discovery of the etiology of tuberculosis as set forth in his two papers. This author had been among the first to controvert Koch's theory of tuberculosis. Somewhat more than a year ago he made the first announcement of his views. In this communication the author advanced a theory of his own, which he believed to be opposed to that of Koch. He maintained that there was no necessity for the action of a specific agent in

the production of tuberculosis, and that therefore such a specific agent could have no rational existence. This position was, in the main, based upon his belief in the discovery of an anatomical peculiarity of those animals known to be especially prone to tuberculosis. This peculiarity he thought to consist essentially in a narrowing of the connective tissue lymph-spaces in certain animals—the scrofulous—and to be either hereditary or acquired. He maintained that the inflammatory process in such animals, whatever the exciting cause, was necessarily tuberculous.

On the occasion of the presentation of his first paper, Dr. Formad had undertaken to demonstrate this reputed anatomical peculiarity by the exhibition, under the microscope, of a number of anatomical preparations. At that time Dr. Shakespeare had regarded that demonstration as far from satisfactory or conclusive. In the first place, no single section showed lymph-spaces. In the second place, the method of preparation followed (that for ordinary histological examination—hardening in alcohol, cutting thin sections, staining these with carmine, mounting them for examination in Canada balsam) naturally was not capable of demonstrating lymph-spaces; not one silver or gold preparation was exhibited. Indeed, this common and satisfactory method of studying lymph-spaces had apparently not even been resorted to, for it was to be presumed that the most positive and demonstrative specimens in the possession of the author were those selected for exhibition. It was true that some of the sections under the microscope showed a cellular hyperplasia of the connective tissue—an appearance by no means new to the scientific world. And this was the sole evidence presented in support of a reputed discovery concerning an important anatomical peculiarity of the lymph-spaces of so-called scrofulous animals, upon which an exclusive theory of the ætiology of tuberculosis had been erected by the author and claimed to be demonstrated.

Recognizing the importance of that reputed discovery, this learned society had at once appointed a committee, consisting of its most experienced microscopists, to examine anatomical preparations which Dr. Formad should lay before it in proof of his announced discovery. Nearly eighteen months had since elapsed, and yet, during all that time, not one preparation had been submitted for examination by that committee.

In the paper at present under discussion, the author had complacently referred for proof of his so-called discovery to the evidence brought forward in his first paper, and supplemented this by *promising* with apparent self-satisfaction the future publication of corroborative observations by some independent investigators. Other criticisms might justly be urged, but, in view of the foregoing facts alone, Dr. Shakespeare believed himself sufficiently warranted in contending that the basis of Dr. Formad's opinion concerning the ætiology of tuberculosis had not been established, and also in suggesting that, instead of that opinion being referred to as a "theory" against the theory of Koch, it was scarcely yet entitled to be dignified by the name of *hypothesis*.

Furthermore, even admitting that this *hypothesis* concerning the anatomy of the lymph-spaces of the so-called scrofulous animals were, by the most indisputable evidence, demonstrated beyond the possibility of doubt, it still contained absolutely nothing which by itself either necessarily supported the conclusion of Dr. Formad regarding the non-specificity and non-infectiousness of tuberculosis, or antagonized the claim of Koch for the specific pathogenic qualities of his tubercle bacillus. When, if ever, this hypothesis became a fixed and determined fact, we should be placed only one step nearer a correct understanding of the ætiology of tuberculosis. The reason of that peculiar *predisposition* which certain animals were known to show toward tuberculosis might then have been satisfactorily ex-

plained. But what the *exciting cause* of that peculiar malady might be was an entirely different question. Whatever this might be, it could be readily understood that its power of destruction would naturally be favored by such an anatomical peculiarity. Such an "anatomical peculiarity," if it really existed at all, could be easily turned to the support of the bacillus theory. The claim of Koch was not that the tubercle bacillus was endowed with pathogenic qualities which under any and all circumstances were capable of exciting tuberculosis. He himself declared that for the calling forth of these powers a suitable soil and conditions favorable to growth and propagation were essential.

Finally, Dr. Shakespeare thought it proper to define his own position with regard to the ætiology of tuberculosis. He wished it to be distinctly understood that it was not from the standpoint of a follower of Koch, who accepted all of that investigator's conclusions, that he had offered the criticisms which he had made. In the consideration of such a grave question as the one then confronting him, he regarded it as obligatory to exact the same degree of rigid proof from friend as from foe, whether advanced on the side of popular opinion or against it. He therefore had not hesitated to express objections to the opinions and statements advanced by his friend.

Dr. Shakespeare admitted, as absolutely established, the power of the tubercle bacillus, under favorable conditions, to produce a genuine and virulent form of tuberculosis. He did not admit that it had been positively demonstrated that no other agent might also be capable of producing the disease; on the other hand, he denied that it had been satisfactorily proved that any other agent was capable of exciting tuberculosis. He believed the proof strong that, under certain favorable conditions, tuberculosis was an infectious disease, and that, at least frequently, the infecting agent was the tubercle bacillus. He saw no valid reason to deny that, under certain favorable conditions, tuberculosis might be conveyed from person to person, and in this sense be termed a contagious disease. Whether or not the tubercle bacillus were regarded as the only agent capable of exciting tuberculosis, its virulence was certainly incomparably greater than that of any other known agent. He therefore failed to appreciate the wisdom or the logic of those who, admitting the virulent qualities and propagative power of the tubercle bacillus, yet, because of a lingering suspicion or even of a decided belief that other agents could produce this terrible disease, would still decline to guard against possible infection or contagion. He regarded the tubercle bacillus, when present, as an infallible sign of the presence and activity of the tuberculous process. On the other hand, its absence, unless after repeated and long-continued searches by competent observers, did not positively warrant a negative conclusion. He therefore saw in the tubercle bacillus an important means of differential diagnosis in obscure cases. From its reported presence in some cases earlier than the physical signs could possibly determine a diagnosis of phthisis, he was inclined to think that it might become of inestimable value to the skillful practitioner to forewarn him of the beginning of that formidable malady which, if curable at all, must be combated from the very onset.

Dr. WOODBURY said that at least two distinct questions had been submitted for discussion: Was consumption contagious, and Was the *Bacillus tuberculosis* the efficient and only cause of consumption? One of these was not necessarily the complement of the other. Consumption might be contagious without being caused by a bacillus, and bacilli might cause consumption without rendering it contagious. The first question he thought should be decided by clinical experience, the second by clinical experience with the aid of morbid anatomy and mycology. Time would permit only a very brief presentation of the arguments in

favor of the views which he held, and he therefore would at once state his conviction, and he believed the experience of others would agree with his own, that pulmonary consumption as ordinarily met with was not a contagious disease. Since the definition of a disorder must be made from the clinical picture presented by the majority of cases, he would say that the typical case of consumption did not present any evidence of possessing a contagious character. The question as to the communicability of consumption under exceptional circumstances he regarded as a very different one from the former. Meningitis or nephritis might be communicated under peculiar conditions, but this would not warrant the clinical teacher in describing them as contagious, at least in any ordinary acceptance of the word. He had seen a number of cases of consumption which had occurred, in members of one family living under the same conditions, but had never met with a single case where the evidence of contagion was conclusive. Even cases of apparent communication from husband to wife, or *vice versa*, could be satisfactorily explained to his mind on other grounds than those of direct transfer of the disease by organic or organized particles. The susceptibility to phthisis might be native or acquired; it could not be transmitted by particulate infection.

With regard to the etiology of consumption, it would appear that there were several varieties of the disease which were indistinguishable by ordinary physical signs. In the first place, there were two classes of cases which stood apparently identical, differing in the microscopical characters of the sputum; one contained the alleged *Bacillus tuberculosis*, the other did not. This led us to a classification of bacillary and non-bacillary tuberculosis. In the latter class of cases, in addition to syphilitic phthisis, pulmonary actinomycosis, and zoogloëtic tuberculosis (a form of mycosis recently described by Malassez Vignol*), there were included cases of ordinary pulmonary phthisis, but *minus* the bacillus. In the first class, therefore, the question arose, "were the bacilli necessarily the cause of the morbid phenomena?" He thought that they were not essential, (1) because it had been shown that consumption might be due to other causes and pursue its course without their appearance, and (2) because they were apparently not a necessary element of tubercle. The bacilli had undoubtedly a certain diagnostic and prognostic value, but their appearance could be accounted for on the hypothesis of their being a mere concomitant of pulmonary consumption, even though it could be shown that they increased its fatality. He was surprised that, with such abundant opportunities for observation, clinical teachers had not been able to convince the world or themselves that consumption was contagious until they were shown something under a microscope. He was more than surprised that Professor Austin Flint had announced his adherence to the new doctrine, that pulmonary consumption was due to the *Bacillus tuberculosis*, and arose in no other way.

Dr. GEORGE HAMILTON said that, after a practice of more than half a century, he had seen no case of pulmonary consumption that could rationally be attributed to contagion. In two or three families, where several members were affected with this disease, attempts had been made to refer it to contagion, but without any sufficient proof. It was to be borne in mind that great repugnance sometimes existed in a family to admitting an hereditary tendency to this affection, scrofula, and certain other maladies.

Dr. DUNMIRE said that on the question, "Whether or not simple inflammation of serous membranes could lead to tuberculosis in the non-scrofulous," he would say that he had the

notes of a case in which the post-mortem proved death to have been caused by phthisis pulmonalis, in which the primary trouble seemed to be the fracture of two ribs on the right side. While both lungs were involved, the pleuritic adhesion of the right side was almost entire. An intimate acquaintance with the family, both before and since the death of this patient, had failed to show any sign of tubercular trouble, and, so far as he knew, none of this connection had died of the disease.

PHILADELPHIA CLINICAL SOCIETY.

Meeting of May 23, 1884.

Dr. HENRY BEATES, Jr., in the chair.

A PUERPERAL CASE WITH NUMEROUS COMPLICATIONS was reported by Dr. MARY WILLETS. Mrs. H., aged thirty, a primipara, after a normal delivery did well for twelve days. Then, after pain in the back and limbs and chilly sensations, she had a rise of temperature and was attacked with nausea and vomiting. The temperature continued high for two weeks. There was nothing to account for the elevated temperature except a laceration of the cervix uteri and some tenderness around this point. On the twenty-fifth day after delivery the patient complained of pain in her left leg. For more than a week there were pain and swelling both above and below the knee; the pain was greatly increased on pressure and on attempts at extension of the limb, and was in the course of the femoral vein, but careful examination failed to reveal anything abnormal. On the forty-third day, the patient having recovered sufficiently to go down stairs, there was a sudden attack of well-developed mania, the patient being violent at first, but subsequently merely loquacious. This continued two days, and then gave place to somnolence, which lasted five days, after which convalescence began.

Dr. E. E. MONTGOMERY remarked that the case was unusual from the lateness at which the fever appeared. During his present term at the Philadelphia Hospital measures had been instituted to prevent the contact of septic matters with the parturient parts. A solution of corrosive sublimate, one to two thousand parts, was used to sponge the parts with after the expulsion of the placenta, and cloths saturated with the solution were kept in place by absorbent cotton, oiled silk, and a tailed bandage. There had been but three cases of septicæmia during the present quarter.

Dr. ALBERT H. SMITH said the local examination which the reader of the paper had very properly made solved the whole problem. Together with the symptoms, it showed the case to be one of pyæmic—not septicæmic—poisoning in a woman feeble and unable to resist the absorption of pus. Septicæmia could not arise after all open surfaces had become purulent. The examination was valuable, and he thought it would be better if more care was generally exercised in this direction.

CLINICAL PHENOMENA FOLLOWING THE PUERPERAL STATE IN TWO CASES.—Dr. PHILIP M. SCHIEDT read a paper with this title. In the first case he was suddenly summoned to the bedside of a woman, aged about thirty-five, whom he found comatose, with the pupils undilated, the head drawn to the left side and flexed on the chest, a clammy sweat on the forehead, and the pulse imperceptible. The heart sounds were faintly detected, and the body and extremities were warm. Restoratives and artificial respiration were without avail, and the patient soon expired. The history of the case, subsequently ascertained from the family physician, was as follows: She had been delivered of a child after a natural labor two weeks previously, which was followed by a normal convalescence unaccompanied by fever or offensiveness of the lochial discharge. Her babe was healthy, and was

* "Jour. of the Am. Med. Assoc.," February 16th, from "Archives de physiologie."

regularly nursed by her, and she was doing so well that her physician had ceased his visits. On the morning of her death she felt unusually well, but about nine o'clock complained of some headache; vomited a little mucus; had a heavy chill; became unconscious, and was found in the condition described, which soon terminated in death. The notes were presented to the society for the purpose of obtaining the opinions of its members as to the cause of death, the writer expressing a belief in its cardiac origin.

The other case was one of *Temporary Blindness following Labor*. After a perfectly natural labor, three hours in duration, the mother failed to see her child when it was presented by the nurse. It was found that she was perfectly blind and irresponsible to the candle test. She remained fully conscious and in possession of her other senses. This continued three days, and was followed by gradual and complete recovery. During this time there was nothing otherwise abnormal in her condition. There was no œdema, therefore no examination of the urine was made. Previous to confinement she had been well able to attend to her duties.

Dr. L. BREWER HALL, in discussing the second case, said the most plausible explanation of such rapidly disappearing blindness was œdema, giving rise to choked disc. The cases reported had not been properly examined by an ophthalmologist, an omission frequently inexcusable. Some patients did not get well, and then we found an atrophy of the optic nerve. He had seen quite a large number of hysterical cases, at times unicolor, and such cases were easily diagnosed by feints and attempts to discover that the patients did see, while off their guard. Some one should always be called in in these cases to make an ophthalmoscopic examination.

Dr. SMITH acknowledged the want of exact information, while the uræmic origin of such cases had been assumed.

Dr. G. BETTON MASSEY denied the necessity of assuming that cases of hysterical blindness were mere malingering. Such patients at times might be perfectly honest as to their inability to see, the real condition being one of divorce between the volitional and the intellectual powers of the mind.

TRACHEOTOMY IN CROUP AND DIPHTHERIA.—Dr. MONTGOMERY read a paper based on an experience of twelve cases, in one of which, a case of diphtheria, the patient had recovered and was exhibited to the society. Five of the operations were for diphtheria, the remainder for croup. In all, the operation was one of last resort, and the series taught the importance of early operation. Death occurred most frequently between the third and fourth days; one patient died in fifteen hours, a second in thirty-six hours, and another on the ninth day. In the successful case the cannula, owing to laryngeal spasm, remained until the twenty-fourth day. In operating, he gave chloroform, and avoided hemorrhage by transfixing a fold of skin held by himself and an assistant, making an incision an inch long, completing the dissection to the trachea by the forceps and grooved director. After opening the trachea, care was observed to remove all membrane previous to inserting the cannula. The after-treatment consisted in attentions to the tube, keeping several thicknesses of tarleton wet with hot carbolized water over it. The temperature of the room was maintained at between 75° and 80° F., and stimulants and good food were given, together with quinine, tincture of chloride of iron, and corrosive sublimate—the latter in frequently repeated doses. The attempt was made to dispense with the tube from the fifth to the eighth day, but it should not be removed until respiration *per vias naturales* was fully established. From these cases he drew the following conclusions: 1. That tracheotomy is justifiable in diphtheria as well as in croup. 2. That it should be performed in croup when it is evident that drugs do not control the progress of the disease,

particularly when there is depression of the lower end of the sternum during inspiration; in diphtheria with the advent of suffocative symptoms. 3. That in the performance of the operation the knife should only be used to incise the skin and trachea, the intervening tissue being torn by director and forceps. 4. That the subsequent use of proper drugs will promote a favorable result.

Dr. COLLINS recalled several flattering cases which in a few days showed crape on the door. He doubted the propriety of anæsthesia, but thought the operation justifiable if only as a means of procuring easy death.

Dr. W. H. PARISH said this operation, which was one of the easiest in performance, should be resorted to whenever the symptoms were of such a character as to show impending suffocation. To determine this required no little judgment, and he recalled a case of recovery without operation where both himself and Dr. Allis had agreed it should be performed. He treats diphtheria by large doses of chlorate of potassium and iron.

Dr. W. H. WARDER, in discussing the treatment of diphtheria, thought the chlorate of potassium and tincture of chloride of iron most successful in ordinary cases. In more malignant ones he had resorted to calomel in five-grain doses. In a case which Dr. Pepper had seen with him the latter advised a continuance of this plan for forty-eight hours. At the end of this time forty grains had been taken, a large and offensive evacuation followed, and the child recovered. He did not think such large doses usually necessary, however. Much of the calomel passed without other change than oxidation.

G. BETTON MASSEY, M. D., *Recording Secretary*.

Miscellany.

THERAPEUTICAL NOTES.—*Three New Anti-syphilitic Remedies*.—The "Revue de thérapeutique médico-chirurgicale" (quoted by "Lyon médical") mentions three new remedies against syphilis: *Cascara amara*, baroba, and *Berberis aquifolium*. The *Cascara amara* is a tree of the genus picramnia, found in Honduras. A liquid extract is made from the bark, and is given in doses of forty or fifty drops in the secondary syphilis of adults. Its action is quite prompt, and it has a remarkable tonic effect. It was brought forward by Dr. Frohling, of Mexico, who cured a syphilitic iritis with it in three days. Baroba is found in Brazil. From fifteen to sixty drops of a liquid extract made from the leaves are to be given daily. This extract, which was made use of by Camille Weber, of Leipsic, and by Edison, in inveterate forms of secondary syphilis, is now recognized in the French pharmacopœia. It is a valuable anti-syphilitic, having also evident tonic properties. The *Berberis aquifolium* comes from Tennessee. Baird, of Moscow, advises the use of an aqueous extract in conjunction with iodide of potassium.

Amorphous Borate of Quinine is recommended by Finkler and Prior, of the medical clinic of Bonn ("Dtsch. med. Woch.," "Centralbl. f. d. ges. Therapie"). It is described as a yellowish body, not so bitter as the usual salts of quinine, and soluble in about its own bulk of water. It was used by the authors in doses of from seven to fifteen grains, repeated every hour or half-hour, so that about forty-five grains were given within from two to four hours. It seemed to be borne best when diluted with a considerable quantity of water, and when a little wine or cognac was taken after it. It did not give rise to digestive disturbance, and the tinnitus aurium caused by it appeared to be less than that which is produced by the ordinary salts of quinine. Its efficacy was tested in typhoid fever (five cases), septic fever (in a case of suppurative spondylomyelitis), erysipelas, pneumonia (three cases), phthisis, and trifacial neuralgia. As regards reduction of temperature, its action is slower than that of the common salts of quinine, but

more persistent. In the case of trifacial neuralgia, thirty grains were given the day before an expected attack, and the attack was notably ameliorated. For six days more the patient took seven grains daily, and no more attacks occurred.

Sclerotinic Acid in the Treatment of Epilepsy has been tried in twelve cases by M. Bourneville and M. Bricon ("Progrès médical"), and improvement was witnessed in only five of the cases, so that the authors do not think the remedy can be said to hold out much hope. They gave it both hypodermically and by the mouth. It was noticed that most of the patients lost weight, an effect which the authors can not explain.

Iridin in the Vomiting of Pregnancy.—At a recent meeting of the Paris Société de Thérapeutique, M. Gueneau de Mussy ("Progrès médical") spoke of the enthusiasm which he had found among the Edinburgh physicians in regard to the use of iridin in the treatment of the vomiting of pregnancy. Dr. Berry Hart, who had used it in ten cases, without a single failure, gave it in the form of pills, each pill containing three grains of iridin, with a sufficient quantity of conserve of roses. A pill is given every night, followed by a saline cathartic in the morning. Considering the histological change undergone by the liver during pregnancy, M. Gueneau de Mussy thought the action of the remedy probably depended on its chologogue property.

Euonymin as a Chologogue.—On the same occasion M. Gueneau de Mussy stated that he had found the following pill an excellent chologogue, given every night:

Euonymin	$\frac{2}{3}$ to $\frac{1}{2}$ of a grain;
Resin of podophyllum	$\frac{1}{10}$ to $\frac{1}{6}$ "
Extract of hyoscyamus or of belladonna	$\frac{1}{4}$ "

The Treatment of Biliary Colic.—M. Blondeau stated at the same meeting that he treated hepatic colic with the following pills, giving from one to three daily:

Extract of hyoscyamus } each	$\frac{1}{2}$ of a grain;
Extract of nux vomica }	
Resin of podophyllum	$\frac{1}{2}$ "
Soap	$\frac{1}{2}$ "

Terebinthinate Vapor Baths for Dysmenorrhœa and Leucorrhœa were the subject of a paper read by M. Brémoud at the same meeting. He had observed that the process was accompanied by the disengagement of ozone, which could not but be beneficial to the general nutrition. In the discussion, M. Constantin Paul remarked that he had known the baths to act well as an emmenagogue in women who were inclined to grow stout, but he wished that the reader had been more explicit in speaking of leucorrhœa, which was only a symptom. As for ozone, it could easily be made by inexpensive processes.

Water Aerated with Oxygen.—M. Dujardin-Beaumez mentioned at the same meeting that he had been employing water aerated with oxygen, instead of carbonic acid, in the so-called "siphons" used for mineral waters. He thought that, on account of the disinfectant property of oxygen, water so impregnated would make a good wash for wounds and for the throat in cases of diphtheria. Besides, it was a promoter of digestion.

The Turpentine Treatment of Diphtheria.—Satlow ("Jahrbuch f. Kinderheilk.," "St. Petersb. med. Woch.") relates his experience in forty-three cases, eight of the patients being adults and thirty-five children. Only one died, a child five years old, who died of paralysis of the heart on the sixteenth day. The cases were all diphtheria proper, the author having had no experience with the treatment in the so-called scarlatinal diphtheria. In the patients who recovered the following complications occurred: Invasion of the larynx (three cases), nasal diphtheria (three cases), persistent albuminuria (one case), transitory albuminuria (six cases), hæmaturia (one case), diphtheric paralyseis (four cases). The complications, therefore, were most commonly renal, but whether or not they were due to the remedy the author is uncertain, for renal complications are common in diphtheria. In addition to the oil of turpentine, the usual treatment for diphtheria was employed, but there was no case of tracheotomy. The turpentine was used in large doses—a teaspoonful for children, even those under five years of age; a dessertspoonful for older children; and a tablespoonful for adults. It was always discontinued as soon as the disease began to improve, or as soon as stranguy was complained of, and the renal

symptoms disappeared when it was stopped. The dose caused a sense of burning in the throat, a feeling of oppression in the stomach, and in a few instances vomiting. These effects were mitigated by giving copious draughts of milk or wine after the medicine was swallowed, and, toward the last of the trials, by mixing the turpentine with one-fifteenth its bulk of sulphuric ether. The first beneficial effect of the remedy was a disappearance of the fœtor, even in gangrenous cases; then the edges of the patches swelled up and became softer, the submaxillary glands grew smaller and less tender, and the soreness in the pharynx became less. No effect was produced upon the fever.

A Caution concerning Chloroform and Strychnine.—Dr. E. Garraway writes to the "British Medical Journal" that a prescription calling for a fluidrachm of solution of sulphate of strychnine, three fluidrachms of spirit of chloroform, and water enough to make a fluidounce and a half, was put up for a lady, with directions that a teaspoonful was to be taken three times a day in water. On taking the final dose, which tasted unusually hot, the patient was seized with spasmodic contraction of the extensors of the feet and legs, which soon passed off, although alarming at the time. On his being shown the bottle, a drop or two of water was seen remaining in it, and beneath this a globule of chloroform which proved to be highly charged with strychnine. His explanation is that more chloroform was ordered than the water would take up, and the surplus, being a ready solvent of sulphate of strychnine, took up a large amount of the salt and fell to the bottom.

THE ILLINOIS MEDICAL PRACTICE ACT.—Recent decisions in two cases—one under the Act to Regulate the Practice of Medicine in Illinois, the other under the Dental Surgery Act—sustain the right of the Board of Health to determine the status both of a college and of a practitioner. Under the latter act the Supreme Court refused the petition of Isaac N. Sheppard for a writ of mandamus to compel the State Board of Dental Examiners to issue him a certificate or license based upon a diploma of the Indiana Dental College. The board refused the license on the ground that the college was not a "reputable" institution.

It was argued that the law constituted the board judges of the standing of a college, and that there was no power of review vested in any other body. "If the board should arbitrarily or unreasonably abuse their discretion, and refuse a license without any reason therefor, there was a remedy for such abuse of a discretionary power. But there was no ground for maintaining that this was the case in the present instance. The board, in its judgment, had decided that the curriculum of study and requirements for graduation of the Indiana Dental College were not such as to entitle it to be classed as a 'reputable dental college'; and there was no power in the law given to any person or body to review and set aside, or confirm, the exercise of the discretion by the board. The petition for a mandamus was denied.

In the case of the State Board of Health against C. Buel Rice, of Cincinnati, a graduate of the Medical College of Fort Wayne, tried in the Sangamon County Court, the defense set up the plea that, being a graduate of a "legally-chartered medical institution in good standing," the defendant was entitled to the certificate of the board; and that it was not competent for the board to inquire into the moral or professional character of such graduates. On the part of the prosecution it was shown that charges had been presented to the board, alleging that Rice was in the employ of, and associated with, the "K. and K. Surgeons," a firm of advertising quacks, and that in various ways connected therewith his conduct was unprofessional and dishonorable within the meaning and intent of the Medical Practice Act. Upon these charges the board had refused to issue Rice a certificate until he had disproved the same. Instead of making any attempt at such disproof, Rice continued to practice; whereupon he was arrested for practicing without the necessary certificate. The facts were admitted by the defense, but, as already stated, the Court was asked to dismiss the suit on the ground that it was obligatory on the board to issue its certificate to the possessor of a genuine diploma of any "legally-chartered medical institution in good standing," regardless of the moral or professional status of the individual. This the Court declined to do, but found the defendant guilty, and assessed a penalty of fifty dollars fine and costs.

Lectures and Addresses.

THE MODERN PHYSICIAN THE MEDI-
ATOR OF SCIENCE.

AN ADDRESS DELIVERED AT THE ACADEMY OF MUSIC, BROOKLYN, MAY 21, 1884, BEFORE THE GRADUATING CLASS OF THE LONG ISLAND COLLEGE HOSPITAL.

BY THE REV. ALBERT J. LYMAN, OF BROOKLYN.

MR. PRESIDENT, GENTLEMEN OF THE FACULTY, MEMBERS OF THE GRADUATING CLASS: The courtesy which permits one of the younger men in the ranks of another profession, foreign, though not alien, to that so honorably represented here to-night, to say a word before the graduating class of the Long Island College Hospital, must also pardon the insufficiency of any possible response I can make to that courtesy. For I can stand here appropriately neither as adviser nor as lecturer. I suspect I am not old enough for the one office nor wise enough for the other.

A year ago, upon your last anniversary, the wide experience and genial sagacity of a gentleman whom Brooklyn respects and honors—the accomplished Rector of Holy Trinity Church—were illustrated upon this platform in an address replete with practical counsel. He crowded the hour and crowned it with good advice. He described the doctor's duty to the people, and the people's duty to the doctor, and put the whole case between the two in such a pungent way that since that speech I do not suppose a patient's case has been neglected, or a doctor's bill remained unpaid in the entire city of Brooklyn.

But good advice is completed when Dr. Hall takes his seat, and I certainly shall not run the risk of shuffling along in his maturer footsteps. Not that the epoch of graduation is unsuited to receive advice. On the contrary, no feature is so admirable in the behavior of the student about to take his degree as the equanimity with which he is able to absorb the vast tide of good advice upon which that degree is floated into his hands. And, on the other side, his friends are equally ready to give their counsel to him. It is impossible to look at a young graduate and not want to advise him. In this Academy to-night, to say nothing of the graver aspect of the Faculty, the personal congratulations of the hour are full of latent admonition. The masculine handshake and the feminine smile come to you thus freighted. Cautions, warnings, suggestions, practical nuggets, points on behavior in the sick-room and out of it, wise saws, pithy reminders, short recipes for success, are flying about your heads at this moment like *confetti* at a Roman Carnival.

Their presence is not a slur upon your ability of self-guidance, still less a token of distrust in you; they are rather tokens of the interest with which your college and your city regard you; they are more than that: they constitute a testimony to the critical and even sublime character of that instant when, after long preparation, a man is fairly launched upon the arena of his profession, and starts with a thousand competitors in the race of his life.

On the other hand, still less can I assume the office of

lecturer and usurp the place of gentlemen who from a more strictly professional standpoint have addressed you, defining your professional ends, describing the sweep of the science you study, and the glory of its achievements.

This is your field and the field of your instructors; and for me to enter it would be worse than carrying coals to Newcastle. It would be *stealing* the coals before carrying them. It would be like presenting second-hand pill-boxes to the Long Island College Hospital—an institution that never takes anything second-hand.

You perceive, then, gentlemen, my unfortunate position. Unable to adopt the rôle of adviser on the one hand or lecturer on the other, I am somewhat in the position of the husband of the Irish shop-mistress, who said that she married her husband "nayther for love nor for money, but for the pure convanience of the shop." My only resort must be to the "convanience" of the moment. In other words, I must simply speak straight out to you my own fellow-feeling and good wishes as one man may to another. And, standing within the inclosure of an adjacent profession, near enough to your own for us to talk to one another "over the fences and between the slats," I may perhaps venture also to offer a remark or two upon a feature of the medical profession in our time which has warmly attracted my admiration, and which, if I mistake not, is more and more attracting and commanding the attention of society at large. I refer to what I may call, if you will permit a long phrase for a simple idea, the *mediatorial office of the modern physician*, as between pure science on the one hand and the practical life of society on the other—i. e., popular philanthropy and public reform.

In our time and land science is both in correspondence and in curious contrast with the popular spirit. The present age is distinguished by the rapidity with which public tendencies take on organized form. You remember Dickens's rattling description of Tom Pinch on the stage-coach bowling up to London, and the growing excitement as the great city came nearer. Some such excitement seizes on a student as he looks out upon the arena of American public life. Its movements are bewildering. The abrupt financial whirlwind of last week is only one of many exhibitions of the power and instantaneous stroke of the forces that are playing through the fabric of our society. Men stand or fall together. Interests are complex and consolidated. Public feeling forms rapidly, and is decisive and formidable. In the midst of this foaming sea of popular currents and practical enterprises, science presents herself with her separate technique, her patient processes, her eternal reserve. As between the two, science and society, the time calls for a mediator. Let me, then, briefly indicate one or two reasons vindicating that title which, in the rapidly forming judgment of thoughtful men, the modern physician is coming to wear—the title of the *mediator of science*.

By this I mean much more than the truism that a physician applies his own knowledge in his own field. This is true, of course. Physicians are practical men. Mere theorists are not physicians. Your college repudiates dreamers as promptly as it does drones. You do not enter the sick-

room to expound therapeutics, but to apply it. You are not there to read monographs upon the *Bacillus tuberculosis*, but to alleviate, so far as possible, the consumptive's pathetic decay. There is such a thing, however, as overdoing the practical. The accurate picture of what the true practitioner is *not* is well given in a little story of the war. When the low improvised shanties were set up in the New York City Hall Park as temporary hospitals, one blazing-hot afternoon a fussy, elderly matron came into one of the wards, bearing an immense bottle of bay-rum. On one of the cots lay a grim-looking soldier, minus an arm and part of a leg. As she approached the cot the following colloquy ensued:

"Good afternoon, sir," He nodded. "You must be very uncomfortable this hot afternoon." "Not so very." "Wouldn't it refresh you if I should sponge off your face with bay-rum?" "No, mum, I guess not." "I think it would. I am *so* interested in the poor soldiers; it would be *no* trouble to do it." "Well, mum, if you want to so much, then fire away." And away she fired, and sponged and sponged until she was exhausted. "There, now, don't you feel very much better?" "No, mum, I can't say as I do." She, with a little temper, and drawing on her gloves, "Well, I should think you would. I should think you would appreciate what is done for you. I don't suppose you ever had anybody sponge off your face before." "Yes, mum, this makes *thirteen* times I've been sponged off to-day, mum. I've notched 'em with my knife on that 'ere cheer where your bottle is"—reaching out his remaining arm and counting, "one, two, three. Yes'm, it's just thirteen times I've been sponged off to-day."

Further, also, of course, the cultivated physician is the supreme *arbitrator* in his own field. What we say of the physician is this: first train him, then *trust* him. Within his own sphere, the physician is and must be an autocrat. "It can not be better done," said the architect when somebody found fault with his cathedral. This, within limits, is the legitimate professional spirit. Dr. Abernethy, perhaps, carried the autocratic spirit to an extreme. When a lady told him that whenever she lifted up her arm it pained her exceedingly, "Then what a fool you must be to lift it up," he replied. Nevertheless, your college intends to equip you with an authority which, in its own domain, should be as unimpeachable as that of a general in a battle.

All this is a truism. But by mediatorship I mean much more than this practical supremacy in your own field.

"Humanity sweeps onward," and in nothing more unmistakably than in the power of discriminating and defining the relative duties of the professions. In former times the edges of the professions were blurred and ran together; pedagogues were politicians, and monks were surgeons; but now we are able to fix with approximate accuracy the true point of professional fitness and efficiency—the place of fitness always being the place of power.

And in this clearer modern light the public is coming to recognize a function of the medical profession larger than that of the mere professionalist—a function as difficult as it is novel and honorable. No other profession can so well discharge it, and yet some one must discharge it. Some

one must mediate between science *on the whole* and society on the whole.

Physical science to-day distinctly faces in the one direction ethics and civil law. In another direction science faces philanthropy and public charities. Some one must keep the peace between these three Colossi. We are talking about the conflict between science and religion. This is not the true issue, because the fields are dissimilar and separate. The real *issue*, I will not call it a conflict, is, on the one hand, between science and morals, as recorded in public custom and civil law; and, on the other hand, between science and philanthropy, as expressed in public charities. Some one must mediate, to secure good understanding and mutual co-operation between the members of this modern triumvirate. In a word, some one must constitute the vital bond between the cool conclusions of the library and laboratory and the ardent currents of a practical civilization.

Who, then, is so well placed and trained as the physician to accomplish this? He must be a man wise enough, and firm enough, and large enough to do it.

It was said of Count Cavour that "he not only taught Italy the art of government, but also taught Europe that Italy could govern."

So the doctor is the ambassador of science to fields beyond her own; because in his field science may be said to culminate. The human body is the house at the cross-roads, where physics and morals join. It is the peculiarity of your science that it gathers up, combines, and caps all other sciences, while, on the other hand, it is upon you that the sharpest challenge falls of public practical demand.

You are, then, not only on the deck of your own profession, but you are right over the cut-water, where the *entire craft* of modern physical science plows its way into the shifting waves of public sentiment and discussion; or, to change the figure, the modern physician stands at the knot, or—if my friend, Professor Armour, will forgive my poaching for a word—at the "*ganglion*," whither all the scientific strands converge, whence all the philanthropic strands diverge. This thought, if true, is stirring enough to excuse a moment's argument.

By mediator, then, let me say I do not mean a go-between. A middle-man is no more a mediator than a ferry-boat is a bridge. The true mediator must be a man large enough to incorporate *both* of two contrasted sentiments in *their entirety*. And the glory of the physician is precisely this, that he must be and can be complete scientist and complete philanthropist in one.

Is this possible? It is more than possible. It is actual in the instance of the foremost men in your profession to-day. Is it not true that the most brilliant medical discoveries of the age have been made by physicians who are in actual practice? The detection, e. g., of those parasitic marauders which, it is said, form the germs of certain of the deadliest diseases, has been accomplished not by savants but by practitioners. On the road down to Jericho these modern Samaritans have not only succored the wounded traveler, but tracked and caught the thieves.

One is struck with the location of the statue of Sir Robert Peel in London. It stands, you may remember, in St.

Margaret's Square, midway between Westminster Hospital on the west and the Law Courts of Westminster Hall on the east. It is a most appropriate position. At once statesman and philanthropist, Sir Robert's statue seems fitly associated with the institutions of both medicine and law, while away from the statue leads the street known as the Broad Sanctuary, down past the eloquent façade of Westminster Abbey. So, midway between the scientific laboratory and the sick-chamber stands the physician, the only man in our civilization who can stand there—reaching a hand in either direction—incorporating at once the spirit of science and the spirit of sympathy—combining the enthusiasm of the scholar with that of the healer—bringing the delicate and rigid processes of physiology to bear upon social institutions and civil codes—translating chemical hieroglyphics into the vernacular of popular precepts—transmuting the winnowed grain of scientific analysis into the living blooms of public health. The local necrology of the past year is full of noble examples in this regard. Men like Willard Parker and Marion Sims represent a professional ideal ample enough to fully unite the scientific and the philanthropic enthusiasms.

But more than this. The special point of the fact and the argument is this—that it is the *modern* physician who sustains by pre-eminence this peculiar office of mediation. And the reason of such an assertion is plain, because the *occasion* for mediation must arise before mediation itself can exist; and this is a matter of time and developed society. North and South must grow strong enough to separate before Abraham Lincoln becomes possible. Controversy before arbitration! Contestants before peacemakers!

In other words, centuries must roll away. Antagonistic or antithetic sentiments must arise in society, grow, develop, gather volume, overflow into prejudices, crystallize into definite forms, positive creeds, endowed institutions—in a word, become matured, tenacious, and powerful, like two great rival camps in the body politic, before the mediator is called for; but then he is called for.

The mediatorial function of the physician, then, is only just becoming defined. Sanitary science, so called, has been developed within the last two decades. The ancient chaos of medical jurisprudence has but recently emerged into better form. Public sentiment is only just taking shape upon questions of the powers of boards of health and the necessity of legal sanitary regulations.

Why, gentlemen, it is not so very long ago since three spiders hung about a man's neck were supposed to be a cure for the ague, and a wolf's head under the pillow at night a cure for sleeplessness.

In a MS. of the Abbey of Bardney, in Lincolnshire, in 1530, is the following recipe: "To Cure Aches.—Take the juice of camomile, or else the juice of wormwood, and a quantity of sugar and good ale, and drink nine days, and the patient shall be whole by the grace of God!"

This, however, is not quite so bad as the old Saxon cure for fever, which was, "*A live wisp tied to the patient.*"*

* See a work entitled "Leechdoms, Wortcunning, and Star-craft of Early England," published under the authority of the Master of the Rolls, and edited by the Rev. O. Cockayne, M. A.

We might safely consider that a certain cure for laziness, but hardly a cure for fever. Even this, however, is surpassed by the Saxon cure for lunacy. "Take the skin of mere-swine, or porpoise, work it into a whip, swinge the man therewith, soon he shall be well. Amen!"*

But now superstition is dead or decadent. On the other hand, philanthropy is awake, and intelligently awake. Millions of money are going to public charities and boards of health, and even now hundreds of unfortunate sufferers who are afflicted with that most intolerable of diseases, cancer, are beholding their new promised hospital as if already rising in the air.

A great ardor is enkindled for healthful reform, not merely reform, but *healthful* reform. From hygienic lasts for shoes up to the broadest questions of national politics, the real cry is "*Health* in reform," and the public want that official and that candidate who is the best *doctor* for the body politic.

Now, all this force of aroused public sentiment is noblest and strongest in the philanthropic and sanitary field. Almost for the first time, then, a really scientific mediation is made possible, and it certainly is desirable, for public enthusiasm, however generous, is not always wise. It has become imperatively and instantly necessary that some one should speak upon the questions of tenements—questions of hospitals and asylums—questions of epidemics—questions of public charities and of sanitary laws, who can speak with the full authority of science on the one hand and with practical public sympathies on the other. And our civilization and the common thought of thoughtful men are bringing the physician to the front as the man, and the only man, to do it.

Or, we may represent the matter in another way. It would seem that the natural history of science traverses a curve, as though a footpath ran over a mountain. And in this curve we may perhaps distinguish *five* posts or stations:

First: That of *observation*.

Second: That of *analysis*.

Third: At the summit, that of *discovery*.

Fourth: That of *specialism* or detailed application.

Fifth: That of *final mediation*.

From the plain of common life the mountain of science thus arises, with two steps on either side its pinnacle. First is the plateau of the observers, men like Audubon the ornithologist. Then come the experimenters and analysts, men like Helmholtz and Huxley. Then at the very summit the great discoverers, the Newtons and Darwins of science.

But nature does not leave the pinnacle of science thus hanging in the air. Nature loves *men*, and so the curve of scientific development bends down again toward the practical, and we enter the zone of the specialists, and then at last the field of those who have, perhaps, the finest mission of all, the mediators—men who, having traversed the entire tract of science, mingle again with the crowd on the plain and constitute the living link between the summits of in-

* "A Chronology of Medicine, Ancient, Mediæval, and Modern," by John Morgan Richards, London, 1880.

tellectual discovery and the varied fields of practical experience.

Here, I submit, is where the profession of medicine is called to stand at the present hour—only remember, gentlemen, that no man is fitted to take that final position of mediator who has not come to it *over the summit*. He must have made the acquaintance of the "*Dii majorem gentium*" of science.

The Long Island College Hospital does not tolerate empiricism. The Long Island College Hospital believes sometimes in cutting, but never in "short cuts." In the course of the twenty-five years of its history this institution has justified its claim to a steadily increasing practical efficiency and promptness of response to public need and demand; and yet, on the other hand, you, gentlemen, and all who have watched the progress of this college, are witnesses that the Long Island College Hospital believes in study before practice, and in mastery before mediation.

No one can conquer Gaul until he has climbed and crossed the Alpine crests. He who slips through underground, the same is a thief and a "quack."

Now the rarer men traverse the entire tract of the five steps we have mentioned. Such men as the German surgeon von Graefe, and Harvey, of England, are at once observers and discoverers, and, still passing onward, they beat and broaden out their special knowledge until it again takes hold of common life and becomes the safeguard of the masses and the guarantee of healthful laws.

It has required a long time to bring all this about, and advance medicine to its present representative position in the scientific world.

The story of mediæval physiology is most grotesque. When preachers were doctors, both professions were spoiled; and practitioners deserved that epithet which Pliny bestowed upon the practitioners of his day, that they were the "only men in Rome who could kill another man with impunity."

In the Middle Ages, astrology was tangled up with chemistry. Mediæval lectures were filled with the fantasies of the cloister. For pain in the joints the Saxon rule was, "Sing nine times this incantation, 'Malignus obligavit, angelus curavit, dominus salvavit.'" In order to stanch the flow of blood a man had to say, "Stupid on a mountain went, stupid, stupid was"—Such incoherent drivel was gravely repeated. Still more simple was the cure for the stomachache, when the physician placed his hand on the man's body and said, "Stolpus tumbled out of heaven." Remedies were surrounded with superstitious rites. The priests were the most popular physicians. To such a gross extent was this *mésalliance* carried that even the Church interfered. At the Lateran Council, in 1123, a decree was made forbidding monks from attending the sick otherwise than in a spiritual capacity. Other decrees followed. At Rheims, in 1131, monks were debarred from attending schools of medicine. In 1215, Pope Innocent III directed an anathema against clerical surgery. No priest was to perform an operation where steel or fire was used. Still the evil continued. The practice of medicine was a fanatical empiricism of the worst kind. In 1345, apothecaries were

united with grocers (as from some of the current adulterations we are inclined to think they are still) and surgeons with barbers. Men's bodies were supposed to be governed by zodiacal signs. Fancies and facts were confounded together. Men watched themselves for occult and whimsical symptoms. They dwelt on their own moods. The vagaries of the devotee were accepted data. For a contusion on the head they pounded a board laid across the feet, so as to "spring the skull back into its place." Medical lecturers were like the cranks and zealots of our day, who narrate their dreams, tell which shoe they put on first in the morning, make morbid confessions, recite harangues which are merely experiments in spiritual vivisection, performed by the demonstrator on himself in the presence of the class, reminding one of that provincial English actor who played Hamlet, and, when he lacked an orchestra, was accustomed to die to slow music, performing on the clarinet himself.

From such a wretched level sprang the lofty curve of modern physiological science. Indeed, we may say that the *whole story* of modern physical science is in physiology, using that word in its large sense. The physician, then, is not a mere specialist. He is the child of the science of the world. The entire history of science—the early fallacies—the speculative perils—the mischiefs of false methods of investigation—the gradual rise of the true method, experimental, inductive, exhaustive—the splendid results of that method—the unearthing of obscure facts—the unraveling of intricate webs—the singling out of critical points in a maze of particulars, the unification of varied phenomena under a single law—all these, which are common features in the history of all sciences, are nowhere more distinctly and compactly shown than in the field of physiology. Then add to this the singularly vital character of the field of physiology itself, occupying the very table-land and crown of nature—its forces nature's finest, its products nature's fairest—and we have reason enough why the modern physician is not only the arbiter in his own domain, but is also called to *mediate on the whole field*—between science in general and the practical sentiments of society. For, gentlemen, certainly all sciences labor for you. Chemistry, with its almost fabulous combinations, and mechanics, with its superb balancings of weights and masses, meet in the wonderful structure which it is your business to study. The paleontologist works for you in his buried rock-world. At the other extreme the biologist works for you, and even the arts of the painter and sculptor aid you, revealing the mystery of life and the perfection of form in this same consummate fabric of the human body whose misfortunes it is your duty to alleviate and whose health it is your privilege to maintain.

Physical science, then, both in the perfection of its methods and in the dignity of its spirit, may be said to culminate in the arena occupied by your profession. Medicine furnishes the metropolitan center. It is the Square of St. Mark's in the Venice of science—to which all scientific knowledge contributes, and in which both the problems and the powers of science are most distinctly shown, while at the same instant, upon the same field, at the very same point of it, you confront the dim and tremendous cerebral phe-

nomena which relate to the moral life, and meet the imperative appeal by which a suffering humanity proffers its incalculable claim. Such a position and such a profession are, in the supreme degree, mediatorial, if any position and any profession can be.

Only one word more, for your patience convinces me that Christian graces as well as medical arts are practiced at the Long Island College Hospital—a word more, directly to yourselves, as members of this graduating class. If there be any truth in the idea which has been thus rudely and hurriedly sketched to-night, I can not conceive of a more commanding ethical motive than it furnishes, as it bears upon the mind of the young physician, inspiring him to maintain a high professional and personal ideal.

For science looks to you not to misrepresent it, while on the other hand society looks to you not to misunderstand it. In this delicate, unprecedented position your profession places you. You are, if one may use a rather dusky metaphor, to pacify the Soudan as well as hold Khartoum. Only *character* can sustain such a position. Ethical soundness—intellectual fairness! You are to be fair to both sides. Other people study ethics. You are to practice it.

A true mediator must within himself *incorporate* his mediation.

It goes without saying, and yet it is worth saying, that the Long Island College Hospital expects every graduate to be a gentleman. May we not also say that science expects every physician to make his manhood true, for in his personality Science embodies herself in her most acute contact with the community. In the fullness and fairness of his character is her claim justified.

I congratulate you, then, gentlemen, upon the profession you are to enter, and the epoch at which you enter it. Your college will look to you to uphold her name and fame. You are to love science and hate shams. In the breadth and accuracy of your knowledge, in the many fidelity of your use of it, you are to illustrate the dignity of your profession, and record its protest against charlatanry, for Humbug dies hard, and, under pretense of panaceas and specifics, mind-reading and faith-cures, and what not, empirics are yet abroad, peripatetic usurpers, whose medical stock in trade is made up as Thackeray says he made up Captain Costigan—out of “scraps, heel-taps, odds and ends of characters.” Such counterfeits, however, only show the value of the true gold. Under the double banner of science and of practical sympathy your college sends you forth to a service whose demand was never more instant, whose prizes were never more noble. From my heart let me say, God speed you, gentlemen! Your mission is delicate and responsible. Be true at once to the science that equips you, and the public that invites you. Bind together those factors of our civilization which narrow men on both sides are forcing into foolish and false antagonism. You are the true Mediators. In your fidelity of private practice you will discharge a sublime public errand. Not only in quieting the pulse of fever and calming the perturbed brain, restoring to the invalid that physical play and repose which seemed to the old Greeks like a music, but in that larger office also to which your profession is summoned in

the stirring and splendid arena of the immediate future, may you fulfill the requisition of that noblest assurance of our holy religion, “Blessed are the *Peacemakers*, for they shall be called the Children of God.”

NOTES ON ALBUMINURIA IN HEALTH.

By GASPAR GRISWOLD, M.D., M. R. C. S.

EVER since the discovery of Bright was made known to the medical profession in 1827, the presence of albumin in the urine has been looked upon as almost positive proof of the existence of disease of the kidneys. This view was unassailed so long as physicians examined the urine only in those cases where dropsy or other renal symptoms had already pointed the way to a diagnosis. In the last few years, however, much attention has been directed to the study of latent Bright's disease, and it has gradually become the habit of many physicians to examine the urine of nearly all patients as a matter of routine practice. Life insurance companies, also, have made it a rule to examine the urine of all applicants, even when they appear to be enjoying robust health. These investigations have revealed the important and even startling fact that albumin may be present in the urine of individuals who consider themselves perfectly well, and have every appearance of being so. Careful observations have shown that in these cases albuminuria may continue for years, or may be transient, lasting only for days or weeks; in other cases it may be intermittent, appearing at certain times in the day, but being absent during the remainder of the twenty-four hours. The question at once presents itself: Are these cases of albuminuria in health to be looked upon as instances of functional disturbance within physiological limits, or as instances of organic changes in the kidney structure which only fail to produce constitutional symptoms because they are not sufficiently extensive? An attempt to answer this question will very properly be preceded by a short consideration of the different ways in which albuminuria may be produced. In the first place, it must be borne in mind that the blood-plasma is constantly oozing through the walls of the capillaries throughout the body, bathing the tissues, and then flowing back through the lymphatics to re-enter the blood circulation at the junction of the internal jugular and subclavian veins in the neck. The capillaries which make up the Malpighian tufts, and those which ramify about the kidney tubules, are an exception to this rule. They are surrounded with an epithelium which, by a selective action, discriminates between the substances which are to be excreted and those which are to be retained in the circulation. So long as this epithelium remains intact, only the constituents of normal urine can escape through the capillary walls; so soon, however, as the epithelium is cast off or becomes degenerated, the blood-plasma, with its albumin and peptones, finds its way into the urine. It is

the presence of the renal epithelium which makes the difference between capillary exosmosis in the kidneys and capillary exosmosis elsewhere in the tissues; when this epithelium has been removed or destroyed, the exposed capillary walls permit the exosmosis of albumin and peptones in the same way that it occurs in the capillaries of the tissues generally. According to Uitzmann, peptones are always present in albuminous urine.

Simple active hyperæmia of the kidneys, without structural change, will not cause albuminuria; the abundant urines which attend hysteria, or follow the ingestion of large quantities of fluid, are never albuminous. Albuminous urine is scanty and high colored when associated with active hyperæmia from turpentine or cantharides; the kidney in such cases presents not only hyperæmia, but also degeneration of the epithelium. It is the latter change which causes the albuminuria. *Passive hyperæmia* involves degeneration of the epithelium as a result of malnutrition by venous blood, the urine becoming scanty as well as albuminous. If the circulation be in any way improved, so that sufficient arterial blood is brought to the epithelium to nourish it properly, the urine soon ceases to be albuminous, and its quantity returns to the normal standard. *Anæmia* causes a similar degeneration of the renal epithelium from malnutrition by blood of poor quality; hence albuminuria often occurs in anæmia, disappearing again as the general health improves. Nussbaum ligated the renal artery for half an hour, rendering the kidney bloodless during that time. On allowing the blood to circulate again, he found the urine temporarily albuminous; the epithelium had degenerated during the period of suspended nutrition, and permitted the transudation of albumin until the fresh supply of arterial blood had restored its normal structure.

Certain substances cause albuminuria in the process of being excreted by the kidneys, probably by involving degeneration of the epithelium. Instances of this are the excretion of biliary principles in jaundice, and the excretion of iodide of potassium when that drug is being taken in large quantities. Under both these circumstances, casts, as well as albumin, are commonly found in the urine. Many other substances cause temporary albuminuria in the process of being eliminated by the kidneys; it is not improbable that the albuminuria which is occasionally present with urines of high specific gravity is due to some temporary degeneration of the epithelium which attends the elimination of an excessive proportion of solid constituents. This would be analogous to albuminuria produced in the course of *diabetes mellitus*. It is not within the scope of this paper to discuss the degenerations of the renal epithelium which occur in the various forms of so-called *nephritis*; to do that would open up many questions as to the pathology of inflammation. One more proposition, however, must be stated in this connection—that is, the possibility of partially digested food-albumin being eliminated by a sound kidney and producing a deposit with heat and nitric acid. The probability of such an occurrence is suggested by an experiment which shows that, if undigested egg-albumin, diluted with water, be injected into the cellular tissue, or into a vein, it is not assimilated, but is eliminated by the kidney,

and can be recovered from the urine. It may be objected that imperfectly digested food-albumin would not, in the first place, be sufficiently osmotic to be absorbed by the digestive organs. However that may be, all authorities admit that albumin may be present in the urine of health after a meal of eggs, just as glycosuria may follow eating an unusually large quantity of candy. As a result of these considerations it may be stated that degeneration of the renal epithelium, variously caused, and varying as to degree and duration, is the cause of albuminuria in nearly all cases. Variations in the renal circulation do not cause albuminuria, except by first affecting the integrity of the epithelium. There is some evidence which goes to prove that imperfectly digested food-albumin may appear in the urine, and yield a deposit on testing.

This paper will confine itself to the discussion of true albuminuria, of renal origin, and will not touch upon the various forms of false albuminuria due to admixtures of blood, pus, etc. The following is an abstract of some of the literature which has appeared on the subject of true renal albuminuria occurring in health. Uitzmann,* in 1870, reported eight cases of albuminuria occurring in young men in perfect health. The daily quantity and specific gravity of these urines were normal, and no casts or blood corpuscles were ever found; the quantity of albumin was at times considerable. In one instance the albuminuria abruptly ceased after having persisted under observation for two years; no cause could be ascertained for the occurrence of the albuminuria in this case, and its sudden cessation was equally problematical. The patient was at all times in good health, and no change of habit could be assigned as a cause for the disappearance of the albuminuria. In another of these eight cases albumin was only to be found in the urine passed at bedtime, at which time it was particularly concentrated. Sir William Gull,† in 1873, reported a number of cases of albuminuria occurring in anæmic girls at puberty. He desired to call attention to this condition as of common occurrence. The patients presented no other renal symptoms, and all recovered as they became stronger. Moxon,‡ in the "Guy's Hospital Reports" for 1878, reports nineteen cases of chronic albuminuria in children, without other signs of renal disease. Albumin was frequently absent from the urine of these patients for hours; it was most likely to be present after breakfast. All the patients recovered. An Italian author, by name Marcacci,§ reported in 1878 that he could cause albumin to appear in his own urine by exercising with his arms sufficiently to raise his pulse to 115 beats a minute. His urine was never albuminous except after exercise. George Johnson, in the "British Medical Journal" for December 13, 1879, states that albumin without casts is frequently found in the urine of people who believe themselves to be in perfect health. Such albuminuria is apt to be transient and intermittent, and is more frequently present in the afternoon, especially after exercise, hearty eating, or a cold bath. Dr. Johnson be-

believes that albumin might be found in the urine of most people who bathe at the sea-shore and remain in the water until they are blue and shivering. He believes that such albuminuria is a warning against the habit which produces it, and argues warmly against its being considered a trivial matter. Leube* found, among 114 soldiers in good health, albuminuria without casts or blood in 14, after a march. M. P. Fürbringer,† in the "Zeitschrift für klinische Medizin," reports the case of a young doctor whose urine became albuminous under the influence of anxiety and fear. Exercise or food produced no effect in this case. The same author examined 61 children between three and six years of age, and found albuminuria in seven. This albuminuria was in some cases absent for days or weeks, returning without apparent cause, and most frequently present during the afternoon. These children were in an asylum, and were all considered to be in good health. Their daily life was regulated by discipline, and they ate the same food and at the same hours. The urines in which albumin was found presented all variations as regards specific gravity, and were sometimes acid, sometimes alkaline. Henri Leroux,† in the

† Leroux, H., "Revue mens. de méd.," March, 1883.

"Revue mensuelle de médecine" for March, 1883, gives the results of examining 118 little girls and 212 boys in an asylum, all of them being in good health. In these 330 children he discovered albuminuria in 19—10 girls and 9 boys. In 14 of the 19 cases albumin was frequently absent, and when present was found only between one and three in the afternoon, following the principal meal. None of these children with albuminuria were sick, and all were eventually discharged from the asylum in apparently good health. Dr. Munn, in the New York "Medical Record" of March 22, 1879, reports 24 cases of albuminuria accidentally discovered in the course of 220 examinations for life insurance. Half of these applicants for insurance were under forty-five years of age, and all believed themselves to be in perfect health. Repeated examinations were made in these cases, and in two instances casts were found. All the 24 applications were rejected simply because of the albuminuria, the persons being otherwise in good condition.

Finally, H. Senator, in a work on albuminuria published in Berlin in 1882, advances the view that albumin is present in small quantities even in normal urine. This theory is similar to that of Brücke, who maintains that sugar in very small quantity is present in normal urine. In normal urine, however, neither albumin nor sugar is ever present in sufficient quantity to be revealed by the ordinary tests.

This short *résumé* of literature bearing upon the subject shows that a large number of excellent authorities are agreed as to the occurrence of albuminuria in health. In nearly all the cases cited no cause could be discovered. In a small minority of cases anemia at puberty, exercise, cold bathing, eating largely of animal food, and mental strain and anxiety were believed to be efficient causes.

The frequent occurrence of *albuminuria at puberty* has been especially insisted upon by Sir William Gull, as quoted above. The albuminuria which often attends anæ-

mia, both at puberty and at other times, is probably due to degeneration of the renal epithelium from malnutrition by impoverished blood. This is entirely analogous to the changes in the capillary walls upon which depend the dropsy and hæmorrhages which are observed in very severe anemia. This view is supported by the experiment of Nussbaum, which shows that temporary ligation of the renal artery causes epithelial degeneration, and is followed by temporary albuminuria.

It is held by many authorities that *albumin often appears in the urine of healthy people after violent exercise*, especially when the exercise has been closely followed by a cold bath. To test the truth of this view, the author has several times examined the urine of twenty-four healthy men, passed after prolonged active exercise followed, in most cases, by a cold shower bath. In none of these twenty-four cases did albumin appear. The following case is interesting in this connection: A gentleman was examined for life insurance and refused, because his urine contained casts and albumin. Two months afterward he was induced by an agent to make an application to another life-insurance company; his urine was examined and found normal. When on the point of being accepted, the gentleman very frankly confessed to the insurance examiner that he had been refused by the first company on the ground that his kidneys were not healthy. Three times more his urine was examined, and still always found normal. A fifth examination was made of some urine which he passed after a boxing lesson and a cold sponge bath; this specimen was found to contain a considerable quantity of albumin and some granular and fatty casts.

Being now alarmed about himself, although apparently in good health, the gentleman consulted a number of prominent authorities, who all agree that his urine never contains anything abnormal except when he has been taking violent exercise. It then almost invariably contains a considerable quantity of albumin and numerous granular and fatty casts. The authorities consulted by this gentleman have scarcely known what to tell him in the way of prognosis. He feels very well, and only time can show whether he is the subject of a developing *nephritis*, or whether his trouble is merely some condition of the kidney which is excited by exercise but is not incompatible with the continuance of health. This subject needs the careful study of years to settle the question absolutely, but the evidence at hand certainly shows that in a *vast majority of cases albumin is not found in the urine of healthy men after exercise*. The question, therefore, assumes the following form: If fifty men in apparently good health take the same exercise, and albumin subsequently appears in the urine of one of them, the urine of the rest remaining normal, shall the exceptional case be considered to be one of latent disease, or of variation within physiological limits? In the light of our present knowledge, the theory of latent disease seems more probable, and life-insurance companies do not hesitate to refuse applicants who suffer from albuminuria after exercise, even though they be otherwise in good health.

All books upon the urine contain the statement that *albumin may be present in the urine of health after a meal of*

* Leube, Virchow's "Archiv," Bd. lxxii, p. 146.

† Fürbringer, M. P., "Zeitschrift f. klin. Med.," i. p. 346.

eggs. The author has made several examinations of the urine of seventeen healthy men, passed after a meal of eggs. The eggs were in some cases raw, and as many as four were eaten at a meal. In none of the seventeen cases was albumin found in the urine. In the course of these investigations the author found a young physician whose urine contained albumin after eating eggs. On further examination, however, it was discovered that the albuminuria was constant, whether eggs were eaten or not. This case has been under observation for three weeks, and the albuminuria still continues; it has even persisted when no nitrogenized food had been eaten for twenty-four hours. The doctor meanwhile feels perfectly well, and his only symptom is a desire to examine his own urine five or six times a day.

The authorities quoted in this paper prove that cases are not very rare in which albuminuria occurs without other evidences of disease; and that in such cases the albumin is most apt to be present in urine passed after eating, or after violent exercise. While the presence of good health seems to indicate that such albuminuria may be due to mere functional disturbance of the kidneys, yet it must not be overlooked that the symptoms of Bright's disease are mainly due to *renal inadequacy, and not to the local organic disease*. In disease of the kidneys, as in valvular heart disease, no striking symptoms are present until the organ is overcome and fails to perform its function completely. The possibility of slight renal affections, not sufficient to produce inadequacy in any degree, seems to have been too much ignored. The kidney has been studied too exclusively in connection with grave diseases which endanger life, and become conspicuous by virtue of the uræmic symptoms which attend them. The following case illustrates the sudden occurrence of a mild attack of *nephritis* without symptoms: A physician was exposed to a draught of air, and suffered the next day from coryza and some lumbago. Another physician, hearing him complain that his back was stiff, jestingly challenged him to examine his urine and make sure that the pain was not a symptom of Bright's disease. The urine was examined, and, to the surprise of both, contained considerable albumin and numerous hyaline casts, with a few epithelial casts. The physician, although startled, took no precautions, and attended to business as usual. The cold was well in four days, and at the same time the albumin and casts disappeared from the urine. In this case the symptoms were those of an ordinary cold, and would not have attracted attention under any other circumstances than those mentioned. The physician has since that time repeatedly examined his urine, but has never discovered anything abnormal. Five years have elapsed, and he is in perfect health. An instance of *mild chronic nephritis* is the following: A boy suffered from *scarlatinal nephritis*, but made a good recovery. A year or two afterward his urine was examined and found to contain albumin. The boy grew up and became a medical student. During seven years his urine continued albuminous under observation. Albuminuria was absent in the morning, before breakfast, but appeared after eating and during the afternoon. During all this time the young man was well, and worked hard at his studies. At the end of the seven years the albuminuria

ceased, and has not reappeared during the last five years. In this case albuminuria was present only after eating, and yet was evidently due to organic disease, as is shown by the history. These two cases—one acute and the other chronic—are good examples of mild renal affections not disturbing the general health, and tending toward recovery. When the possibility of mild cases of renal inflammation or degeneration is considered in connection with the inability of nearly all healthy men to produce in themselves albuminuria by exercise or diet, it seems probable that the so-called albuminuria in health is due rather to some form of kidney disease too slight to produce general symptoms. A man who has albuminuria after exercise may, perhaps, be compared with one who has hæmoptysis under the same circumstances. The latter may not die of phthisis, nor the former of Bright's disease; both may outgrow the tendency, yet, so long as it continues, neither can be looked upon as a thoroughly sound man.

INTRA-UTERINE INJECTIONS IN PUERPERAL SEPTICÆMIA.*

By LOUIS A. RODENSTEIN, M.D.

WITHOUT desiring to enter into the discussion concerning the use of vaginal or intra-uterine injections as a prophylactic measure after normal labor, I wish to put upon record the five following cases which have occurred in my practice during the past ten months.

They demonstrate conclusively the value of intra-uterine injections in cases of childbed fever, and consequently serve to establish the theory of the septic origin of the disease.

CASE I.—Mrs. K., aged twenty-two, a primipara, was confined March 27, 1883. The head presented, labor was prolonged for twenty-four hours, and she was delivered with the forceps, the child weighing nine pounds and a quarter. The perinæum was not ruptured, the placenta was expelled intact, and the uterus contracted well. Within an hour after delivery she had a severe hæmorrhage, and I introduced my hand and emptied the uterus of clots. I gave ergot and morphine to control the hæmorrhage, and left the patient comfortable.

All went well to all appearances till the night of the 30th (three days later), when the patient had a severe chill, and on the following morning I found her with a high temperature (105° F.), quick pulse (150), flushed face, and very excited state of mind. The lochia had stopped. Ordered vaginal douches of carbolized water, 2½ per cent., night and morning, and five grains of quinine every four hours.

The following morning (April 1st) the temperature was still 105°, the pulse 150, the respiration 46, tongue dry, and she had been delirious during the night; treatment continued. At noon the temperature was 106°, the pulse 160, the respiration 49, with pain and tympanites in the abdomen; ordered poultices and opium. Quinine stopped.

The following morning, April 2d, the temperature was 106°, the pulse 160, the respiration 49. I called Dr. James B. Hunter in consultation, who advised a 2½-per-cent. carbolized intra-uterine injection. This was adopted at once, with prompt amelioration of the symptoms, and was faithfully carried out by Dr. James R. Goffe and myself, at intervals of two, three, and six hours, day and night, for six consecutive days.

* Read before the New York Obstetrical Society, February 5, 1884.

As the report of the case from hour to hour is somewhat tedious, I will briefly outline the points of interest: The wash-water gave constant evidence of a varying amount of fragments of broken-down tissue, grayish, flocculent material, and pus. As the temperature continued to fluctuate between 104.6° and 105.6°, on the night of April 3d the rubber ice-coil was applied to the abdomen, with the effect of reducing the temperature in two hours and a half from 105.6° to 101°. In spite of the almost constant use of the coil, however, and the frequent injections, the temperature could not be reduced again below 103°.

The presence of abundant débris in the wash-water indicated the probable presence in the uterus of material that could not be washed away (as the temperature still ran high). It was, therefore, decided to explore the uterus with the curette. Accordingly, at 9 A. M. on April 6th, the patient was put in Sims's posture, and with the long, dull-wire curette (which I hold in my hand) I succeeded in removing from the uterus several ragged pieces of decomposing material. After this the patient was placed upon her back and the uterus washed out. The temperature fell promptly from 103° to 99.6°. As the temperature again rose, the injections were continued, the coil was used, and the following day quinine was again resumed, ten grains *per rectum* every six hours.

Two days later, April 8th, the curette was again used and a few small fragments were removed. The temperature reached normal, 98.5°, 4 A. M., April 9th. The injections were continued at longer intervals till April 10th, when they were discontinued and vaginal douches substituted, being used twice each day. The patient took nourishment well during the entire time, consisting of milk, beef-tea, and brandy.

The temperature fell below normal for two days. April 11th the patient had large, greenish, watery discharges from the bowels. I administered bismuth and soda. Liquid nourishment was soon changed to solid food.

And thus ended in recovery a most formidable case of what I considered puerperal septic poisoning. The patient's system was thoroughly saturated with the poison, and the fluctuation of the temperature was due more or less to the working (fermentation) of the septic matter already absorbed. The quinine undoubtedly served to reduce the temperature after absorption had been stopped.

CASE II.—Mrs. H., aged twenty, a primipara, was confined, April 29th, with a cranial presentation. Labor was normal, there was no laceration of the perinæum, and she had every appearance of making a good recovery. On the seventh day after delivery I was called, and found the patient had had a chill three days previous. She had continued fever, a flushed face, a dry tongue, and was very much excited, with a great deal of delirium. There was perfect anorexia; in fact, she had not taken any nourishment for over three days. The usual vaginal washing was neglected. The temperature being 105°, the pulse 150, and the respiration 48, I at once commenced the intra-uterine wash with 2½-per-cent. carbolic solution, and, after only two washings, the temperature became lower.

The patient was the wife of a poor German gardener, and they lived in a little dirty cottage with most unfavorable sanitary arrangements. The mother of the patient acted as nurse, and was instructed to administer milk and brandy liberally every hour during the night. On an early visit the next morning, the uterine washings having been directed to be continued, I found that, as, in the judgment of her friends, she was relieved of her fever and slept so sweetly, she had not been disturbed by either food or stimulants, and had died of exhaustion early in the

morning. The uterine washing evidently checked septic absorption; although but few washings had been used, yet their good effect had been at once shown.

CASE III.—Mrs. I. B. had been confined of her fourth child on November 19th. Her labor was neither a long nor a difficult one; with her third child she had considerable trouble and was torn down to the rectum. She was operated on, but was again somewhat torn. On the fourth day after delivery she had a severe chill and a rise of temperature. Her face was flushed, with some delirium, dryness of the tongue, and suppression of the lochia. I examined and found the os uteri sufficiently open to introduce my finger. I commenced washing out the uterus every six hours, and in forty-eight hours found that the temperature was reduced from 105.4° to 101°, and in twenty-four hours more to normal, so that with sixteen washings I am confident that the course of the disease was stopped, and recovery promptly ensued.

CASE IV.—Mrs. I. V. I was called to her bedside December 14th, to attend her during her tenth confinement, and found an old midwife in attendance. She had delivered her of a still-born male child, and, after waiting a little time for the placenta to come away, she pulled on the cord and tore it from the placenta, and then I was sent for. In making an examination, my finger came in contact with a second child, which I extracted, and then found a third one—all males and still-born. After removing three distinct placentas, I left the woman comfortable.

On the third night she had a severe chill, with fever and delirium.

December 18th,	9 A. M.,	temp.	105.2°,	pulse	155,	resp.	48.

In this case I washed out the uterus three times a day with carbolic solution, gave five grains of quinine every six hours, and pushed milk, beef-tea, and brandy, just as much as the stomach could bear.

The uterus was washed out about fifteen times, and the patient made a good recovery, although for several days considerable albumin was found in the urine.

CASE V.—Mrs. T., aged nineteen, a primipara, was confined of a female child on the 16th of January, after fourteen hours of labor. As the pains died away, I gave ergot without effect, and was obliged to use the forceps. The perinæum was ruptured slightly, but I did not consider it sufficient to require operation. She seemed to be doing well until the morning of the fourth day, when she was suddenly taken with a chill, and every symptom of septic poisoning presented itself. The fever kept up for only three days.

"	23d,	8 A. M.,	98.5°,	"	84,	"	28.

I commenced with the washing of the uterus at once, and

used antiseptic applications on the lacerated perinæum, to prevent any further absorption, as I recognized at once that this must be one of the points, as well as the uterine cavity, of absorbing the poison. Gave five grains of quinine every six hours. I used in this as well as the other cases the Chamberlain glass tube for the intra-uterine injection.

I would add one point, which I have found in my experience, that where there is septic poisoning the os uteri is invariably sufficiently open to readily admit the finger, and remains open until the poison is eliminated, no matter how many days it may be, while, on the other hand, if the chill, rise of temperature, and other symptoms that might appear to be those of puerperal septicæmia are of a malarial origin, the uterus is contracted and the os is closed, as they should be at that period of the puerperal state.

MISSED ABORTION;

SCLEROSIS OF THE PLACENTA.*

By HENRY J. GARRIGUES, M.D.,

VISITING OBSTETRIC SURGEON TO THE NEW YORK MATERNITY HOSPITAL.

MRS. MARIA F., aged thirty, married ten years, has had five children, the last one having been born two years since. She menstruated last in April, 1883, at an unknown date.

She presented herself on December 4, 1883, stating that she had lost a small amount of blood daily for the preceding four weeks. The size of the womb corresponded to a pregnancy of only four months. No sounds, neither uterine nor fetal, were audible. I diagnosed, therefore, pregnancy, with death of the fœtus. I saw her about once a week after that. The bleeding ceased, and she felt well all the time.

On January 9th, about nine months after her last menstruation, a fœtus and after-birth were expelled with moderate pain and with no loss of blood. The whole came away in one mass and was perfectly fresh.

I take the fœtus to be at the end of the fourth lunar month of gestation, but with partial arrest of development. It measures, from the top of the head to the heel, 18.5 cm. The bones of the skull are ossified, but separated by large sutures and fontanelles. With the magnifying glass I see some small hairs appear on the scalp, but there is no trace of any on the body. The cord is inserted between the lower and middle thirds of the distance between the symphysis pubis and the sternum. The eyelids are distinctly marked, but not yet separated. The sex is female, as seen by the considerable distance from the genitals to the anus, a well-developed vagina, and distinct labia majora and minora.

About the mouth we have, I think, an arrest of development. The slit is very large. The lower lip is so short that it only covers half of the lower jaw, and the upper lip has scarcely begun to be formed. There is a considerable distance between the intermaxillary bone and the maxillary bone, while, according to Kölliker ("Entwickelungsgeschichte," p. 475), the connection normally becomes rather intimate in the eleventh or twelfth week. From the nos-

trils an open passage leads outward and backward into the palate, where the space between the vomer and the maxillary bone is yet open all the way through to the pharynx on the left side, but is closed in its posterior part on the right side. There is even yet seen a remnant of the fissure which during the first few weeks runs between the lateral nasal and the upper maxillary processes up to the eye, in the shape of a little notch pointing from outside the nostrils in the direction of the eyes.

This arrest of development in the palate is not uncommon even in the child born at full term, and forms the well-known malformations called *hare-lip* and *cleft palate*.

The epidermis has to a great extent come off, and forms loose gloves and socks on the hands and feet. The soft parts look much atrophied in proportion to the bony ones.

The placenta is oval, measures 8 by 6 cm., and is mostly composed of a hard, whitish, lardaceous mass. The division into cotyledons has disappeared. The fetal surface of the placenta is normal.

The cord measures in all 20 cm., but the last three centimetres of it run in the membranes and on the surface of the placenta, forming the so-called velamentous insertion.

As to the membranes, we remark that a gelatinous tissue, forming masses as large as soft-shell almonds, is found between the amnion and the chorion.

Of the decidua only a few long shreds are found. The cause of the death of the fœtus is to be sought in the condition of the placenta. Instead of a soft, spongy mass composed of villi chorii bathed in maternal blood, we find a hard, uniform, bloodless, lardaceous mass. This condition has been described by Neumann ("Königsberger med. Jahrb.," ii, 1860; quoted by Spiegelberg, "Geburtshülfe," p. 344) as *sclerosis of the placenta*. It is doubtful whether it is due to an hypertrophy of the villi or to an inflammation of the interstitial connective tissue, but it is supposed to be due ultimately to syphilis.

When the fœtus dies, it undergoes either putrefaction or mummification. In the first case it gives rise to fever, and is soon expelled or must be removed, while in the second condition it may be retained for many months, as in the present case, in which it probably has staid for six lunar months in the uterus.

The dwindling of the soft parts need not be attributed to an absorption of the liquid part of the body after the death of the fœtus. Seeing that scarcely any placental tissue is left, it is more reasonable to suppose that the fœtus was for a long time submitted to gradually increasing starvation, by which its soft parts were reduced in bulk just as in adults deprived of food.

The condition of missed abortion presents several points of practical interest. If the fœtus is decomposed, it is dangerous for the woman, and ought to be removed. If it is mummified, no treatment is called for. As there commonly will be some doubt about the diagnosis, so that there might be a living fœtus in the uterus, it is wise to abstain from any measures which favor the expulsion of its contents.

It is of importance to know the possibility of this condition in order to be able to avert unwarranted suspicions, as when a married woman, whose husband has been absent,

* Read before the New York Obstetrical Society, February 5, 1884.

expels a fœtus which represents a period of development of shorter duration than his absence.

Finally, there may be occasion to treat the woman for uterine disease, or, perhaps, both her and her husband for syphilis.

Clinical Reports.

ROOSEVELT HOSPITAL.

CLINICAL REMARKS BY HENRY B. SANDS, M. D.

Heaton's Operation for Hernia.—Excision of the Hip Joint.—Internal Urethrotomy.

CASE I.—This man, gentlemen, has an inguinal hernia, and came to the hospital to be treated by what is called Heaton's operation for a radical cure. On February 4th I injected alcohol into the inguinal canal, and have injected it once since, on the 14th of this month (February). There seems to have been very little reaction set up by the alcohol, and, as the man is in haste to get away from the hospital, I have decided to use the preparation which is recommended by Heaton. This consists of a mixture of the solid extract of white-oak bark and of the fluid extract of the same substance, to which is added a small quantity of morphine. The morphine is added to diminish the pain caused by the injection. This substance causes more irritation than alcohol does, and therefore it is expected to work a more speedy cure in cases which are curable at all by such methods. In operating, it is impossible to say with certainty whether you can reduce the sac or not. The probability is that, unless the hernia is very recent, the sac is not reducible. As to the performance of the operation, it is simple enough, although care is required that the hernia may be pushed back. This can be done with the finger of the right hand introduced into the external ring, invaginating the integument. The forefinger of the left hand is then placed over the external abdominal ring, as nearly in a vertical position as possible, and the spermatic cord is crowded to the inner side. Using the left forefinger as a guide, the hypodermic needle is made to penetrate the tissues lying along the inguinal canal, and, when it is certain that the inguinal canal has been reached, the direction of the needle must be changed, so as to carry it upward and outward toward the internal abdominal ring. Having reached that situation, begin to inject the fluid by pushing the piston down, and, as you force the fluid out, vary the situation of the point of the instrument so as to cause the fluid to come into contact with a considerable quantity of the connective tissue which surrounds the sac. That is the principle of the operation, and it is expected that the injection shall not be made into the sac nor into the peritoneal cavity. Whether the injection ever passes into the peritoneal cavity is not known. At any rate, peritonitis, fortunately, does not result from the operation. I am going to use to-day Heaton's instrument, which is different from the one which you have seen me use heretofore. The point of the needle is a little blunt, and is therefore less likely to penetrate a vein and cause an injection of the fluid into a blood-vessel. The perforation of the needle is about an eighth of an inch from its point.

The patient should be kept in bed a week or ten days after the operation, and, when allowed to get up, he should wear a truss. The operation in this young man's case is not performed with the expectation of obtaining a radical cure of his hernia. That result is very rarely obtained, and only in the case of very

small hernia. But it is done in the hope of so far reducing the size of the aperture through which the hernia passes as to make it easy for him to obtain a truss which will prevent the descent of the hernia while he is at work. This man has been treated by good truss-makers, but they have not succeeded in providing him with a truss which will defend him against a protrusion of the hernia. Therefore he is hindered in his work and subjected to the risk of strangulation. It has been found by Dr. Bull and by Dr. Weir, as well as by others who have had a pretty extensive experience with this operation, that it is capable of conferring this benefit of enabling the patient to wear a truss with success, whereas previous attempts to do so have been unsuccessful.

While the next patient is being etherized I may report to you concerning a little boy who was here three weeks ago, and underwent the operation of excision of the hip joint, and about whom we felt grave apprehensions, as his condition was then very unfavorable. He had no severe symptoms or shock after the operation, and, with the exception of a rise of temperature for the first two days, there has been nothing to report except that he has done well. The discharge has diminished, the boy is able to eat and play in bed, and he has a very fair prospect of recovery from this operation, as he recovered from a similar operation upon the other hip a few months ago.

CASE II.—Another patient with hip disease, which will probably require excision, is about to come into the room for examination. He is a feeble little boy, four years of age, with a very large head, which is possibly hydrocephalic. He came in here for the first time on the 2d of January, 1883, and has recently been readmitted. Some time ago he fell out of bed, striking on his left knee, and from that time he limped. At the end of May a plaster-of-Paris splint was applied in the outpatient department. He re-entered the hospital on the 12th of June, when the left limb was found to be shorter than the right, the diseased limb being adducted and flexed on the pelvis. There was pain on motion and on pressure over the trochanter. The gluteal fold was nearly effaced. These symptoms of hip disease were treated by extension made by a five-pound weight strapped to the foot. This treatment was pursued until September, when it was discontinued, and a plaster-of-Paris splint was put on to immobilize the limb. The patient left the hospital on the 10th of September, but was treated in the out-door department until the time of his readmission, on the 22d of February. Two months ago an abscess formed in the neighborhood of the neck of the femur. It was opened, and since the operation the patient's general health has improved. The urine contains phosphates, and is alkaline; it contains no albumin.

This is an ordinary case of hip disease as to history, and probably as to pathological lesions. The head of the femur is carious, and it is very likely that the acetabulum is also diseased. Absence of crepitation is no proof that the articular cartilage has not been destroyed, because frequently crepitation is prevented either by the limitation of the disease to one of the articular surfaces, or by the presence of granulation tissue, which often exists. The attitude of the limb is characteristic; it is flexed and adducted, and there is apparent shortening. The measurements which were made the other day did not show much real shortening of the left, or affected, limb, but such measurements are very unreliable, because made under unfavorable circumstances. It is difficult to bring both sides of the pelvis on the same level, and the measurements are vitiated by abduction and adduction of the limb.

The occurrence of an abscess almost certainly points to hip-joint disease. Even if the abscess did not apparently communicate with the joint, it was probably articular in the beginning. When the disease has advanced to the stage of suppuration and

tubercular deposits have invaded the bone and the synovial membrane, there is very little hope from any means except excision.

Now that the child is under ether, I immediately, on moving the joint, discover crepitation, which demonstrates erosion of the bony surfaces composing the joint. I shall open the articulation by making a curved incision with its convexity backward, commencing above the trochanter, running behind that process, and then forward. I find, on dislocating the femur, and dividing the bone well down through the great trochanter with the chain-saw, that the tissue is pretty firm at the point of section; and that is encouraging. There is slight erosion of the acetabulum, which, however, is not perforated. The disease seems to be located near the margin rather than in the central part of the acetabulum. I think I have now removed all the carious bone, and I think the case is likely to do well. I shall dust the wound with iodoform, after having washed it out with the bichloride solution through the two drainage-tubes which have been inserted, and then apply an absorbent dressing. After twenty-four hours, an extension apparatus of a weight of two or three pounds will be applied.

I now show you the two patients who were operated upon a week ago for varicocele. In both cases, you may remember, I used a stout catgut ligature, and applied a suspensory dressing of iodoform gauze. Neither of the patients has been ill since the operation; there has been no fever and no suppuration. Instead of the soft and compressible mass of veins which existed at the time of the operation, a hard mass is now felt, nearly an inch in diameter, which is due to plastic deposit. Probably the patients would do perfectly well without another dressing, but, as a matter of precaution, the dressing will be renewed. Had I done the operation by almost any other method than the one which I adopted, it would have been followed by suppuration.

CASE III.—The case now before us is one of considerable interest of its kind, the patient having been treated for urethral stricture in this hospital some years ago, and having passed through a good many attacks of urethral fever and abscess which threatened his life. He is from Massachusetts, a boatman, fifty-seven years of age, who re-entered the hospital on the 11th of this month. A brief abstract of his history shows that he has had three attacks of gonorrhoea. He also had a stricture which caused retention of urine, and a perineal abscess. My colleague, Dr. Weir, performed both internal and external urethrotomy. No guide could be passed into the bladder before the perineal tissues were divided. After the operation the patient had fever and chills, was extremely prostrated, and remained for a long time in a precarious condition. After leaving the hospital he continued to have a slight discharge from the urethra. He passed a sound (21 French) for a time, but has not continued regularly in the use of it, as he was advised to do, and there has occurred what is a common event—namely, a recontraction of the stricture. He came into the hospital on the 11th inst., with redness and swelling of the testicle, and pain in the perineum. An opening formed midway between the scrotum and the anus, through which about one half of the urine now escapes. On one occasion I was able to pass a filiform bougie through the strictured urethra into the bladder, but, when the attempt was again made, no instrument whatever could be passed. It is proposed to-day to perform internal urethrotomy, provided the urethrotome can be introduced.

After distending the urethra with oil and introducing several filiform bougies, I have at last been able to pass one on into the bladder, and also the metal guide of Maisonneuve's instrument, which follows it. In introducing the latter, great gentleness should be observed, as I have known a careless operator to make a false passage into the rectum. The cutting instrument

will now be passed, dividing the strictures, which are found to be very numerous and tight. Notwithstanding the largest cutting blade has been employed, the urethral walls are still rigid. I am able, however, to pass a silver catheter (No. 19) into the bladder, and to withdraw a few ounces of urine which it is found to contain. The patient will be confined to his bed for the present, and no instrument will be introduced into the urethra before the lapse of a week.

Book Notices.

On the Discovery of the Periodic Law, and on Relations among Atomic Weights. By JOHN A. R. NEWLANDS, F. I. C., F. C. S., Member of the Society of Public Analysts, etc. London: E. & F. N. Spon, 1884. Pp. viii-39.

This little book is simply a republication of the different papers contributed by the author to various scientific periodicals since 1864, all tending to support his claim to priority in the discovery of the law of the inter-relation of the elementary atomic weights, which usually goes under the name of Mendeleeff's law. Apart from any historical importance which may be attached to these lucubrations, they are of some psychological interest as showing the successive phases which an hypothesis may assume in the mind of its promulgator during the process of its evolution.

The Cinchona Barks Pharmacognostically Considered. By FRIEDRICH A. FLÜCKIGER, Ph. D., Professor in the University of Strasburg, etc. Translated from the Original Text, with some Additional Notes, by FREDERICK B. POWER, Ph. D., Professor of Pharmacy and Materia Medica in the University of Wisconsin. With eight lithographic plates and one woodcut. Philadelphia: P. Blakiston, Son & Co., 1884. Pp. 101. [Price, \$1.50.]

A MONOGRAPH which comprises about all that is known in regard to the cinchona bark offers little material for criticism. Especially is this the case when the compilation is made by a man so competent as Professor Flückiger. The book contains, in fact, a description of the varieties of the plant, and their differential botanical diagnosis; their habitat; the methods of their cultivation and of the collection of the barks; the structure and chemistry of the latter, including an account of the chemistry of the various alkaloids; and an historical review of the subject of "cinchonology," with a copious bibliographical index. Some important additions have been made by the translator in regard to the quantitative estimation of the alkaloids. The work is of sumptuous appearance and elegantly illustrated.

Some Account of Cardiac Aneurysms. Being the Bradshawe Lecture, read before the Royal College of Physicians of London on August 18, 1883. By J. WICKHAM LEGG, Fellow of the College. London: J. & A. Churchill, 1884. Pp. ix-75.

This is a masterly dissertation, and includes descriptions of all the lesions, as found in the left ventricle (the most common), the right ventricle (rare), the left auricle (nearly all general aneurysms of the auricle), the right auricle (very infrequent), the muscular septa (of the auricles, one case; of the ventricles, not at all common), the "undefended space" (exceedingly interesting to the anatomist and to the pathologist), the valves of the heart, and the cardiac coronary arteries. The lecture occupies fifty-seven pages, and is followed by a bibliography. Speaking of the causes of aneurysm of the left ventricle, the author

gives an interesting and concise description of two forms of myocarditis, or fibrous degeneration, and contests the view, advanced by Virchow, that they are due to syphilis.

Quarterly Report of the Chief of the Bureau of Statistics, Treasury Department, relative to the Imports, Exports, Immigration, and Navigation of the United States, for the Three Months ended September 30, 1883; also containing Other Statistics relative to the Trade and Industry of the Country. Washington: Government Printing Office, 1883. Pp. iv-133.

Correspondence.

LETTER FROM WASHINGTON.

The Proposed Fireproof Building for the Army Medical Museum and Library.—Homoeopaths' Aspirations.—Sanitation and the Customs Service.—The Health Officer of Calcutta on Cholera.—The Bureau of Animal Industry.

WASHINGTON, June 16, 1884.

SINCE my last letter the Senate has passed without debate the bill providing for a fireproof building for the Army Medical Museum and Library. It is understood that plans have already been prepared for the erection of the building. In case the House concurs in the action of the Senate, we may hope soon to see this superb monument of the liberality of the nation in more fitting quarters.

The homoeopathic sect are bestirring themselves to induce Congress to concede them representation in the Army, the Navy, and the Marine-Hospital Service. Petitions have been presented in the Senate from New York, Illinois, Ohio, New Jersey, Kansas, Georgia, and Michigan, praying for the recognition of the sect, and setting forth that they are now debarred from appointment into the public service. The petitions have been referred to the Committee on Civil Service and Retrenchment.

The Treasury Department has published at length the opinion of the Attorney-General relative to the rights of inspectors of customs at local quarantines, from which it is concluded that the Government has a peremptory right to protect the public revenue by stationing an inspector at the quarantine, and such officer must subject himself to the necessary quarantine regulations.

Surgeon-Major McLeod, the health officer of Calcutta, has made his quarterly report to the "Chairman of the Corporation of the Town of Calcutta," under date of April 12, 1884, and in that report he mentions Koch's experiments in the search of the cholera bacillus, which are highly interesting as viewed from a local standpoint.

"In the preceding quarter, cholera had broken out severely in October, abated in November, and reached a very low level in December. The abatement reached its minimum in January, which presents a more favorable result than any January of which a record exists. In February, however, the disease began to resume its wonted dimensions. Throughout the month of March a steady rise took place, and the total of this month is higher than that of any March since the year 1869. The year

that comes nearest to it is 1876, with three hundred and twenty-four deaths. The total, though unprecedented in recent years, is still considerably below the mean of years preceding 1870. This large and sudden rise of cholera has been coincident with an unusual absence of rain and a prolonged drought. The disease commenced to increase when the weather began to get warm, and with the change of monsoon a decided advance was observable, which has been progressive up to the close of the quarter. The absence of rain implies increasing impurity of tanks and wells, owing to subsidence and evaporation. It means also a gradual drying up of filthy drains and cesspools; when this drying up is complete, the filth gets pulverized, and is converted into dust, which fills the lower strata of the atmosphere of the town and enters the lungs and stomach along with the air that is breathed and the water and food. Moreover, the prolonged drought causes subsidence of the soil water, and various decompositions take place in soil recently soaked, which are now recognized as conditions of grave peril to health. The detection by Dr. Koch (who was deputed by the German Government to inquire into the causes of cholera, and prosecuted his researches in our midst during the last cold weather) of a micro-organism or bacillus which is invariably found in the intestinal canal of persons laboring under the disease, and in no other disease, is a notable incident belonging to the sanitary history of the period under report. Dr. Koch also found this same comma-like bacillus in the waters of a tank at Ballighatta, in the suburbs around which cases of cholera had occurred. Whether this organism is the cause of cholera, and whether it existed in the tank before the cholera commenced in its neighborhood, or found its way into it along with the excreta of the sufferers, are questions which must be settled by further research. But, whatever may be the special and immediate cause of cholera, it seems certain that the conditions above specified profoundly assist in the development of the disease; and a larger supply of pure water, a better system of conservancy and drainage, and the filling up of tanks and wells, must still be looked upon as the principal means of reducing the incidence of the disease. I may likewise record here the fact that Dr. Richards, Civil Surgeon of Goulundo, has proved by experiment that cholera excreta are, under certain circumstances, fatally poisonous to pigs. Dr. Koch failed, both in Egypt and in Calcutta, to impart the disease to animals, either by means of the crude discharges or pure cultivations of bacillus. Dr. Richards's success in poisoning pigs with cholera evacuations opens out an additional field for research."

The act providing for "the establishment of a bureau of animal industry, to prevent the exportation of diseased cattle, and to provide means for the suppression and extirpation of pleuropneumonia and other contagious diseases among domestic animals," became a law on May 29, 1884. The objects of the law are apparent in the somewhat voluminous title given it, and the work is to be done by a veterinary surgeon, who is to be the chief of the new bureau, and act under the general direction of the Commissioner of Agriculture. The cattle quarantines are distinctly retained under the control of the Treasury Department, so far as exportation or importation is concerned. When it becomes necessary to quarantine diseased cattle on a farm in the interior, the Commissioner of Agriculture is empowered to act. Special investigations into the causes of contagious diseases among the domestic animals are also to be conducted. A heavy penalty is placed upon railroads and other common carriers in case they are convicted of transporting diseased animals from one place to another. This law ought to have the effect of showing to foreign countries interested that the Government is in earnest in the attempt not only to prevent the exportation of diseased meat, but to prevent the disease as well.

THE
NEW YORK MEDICAL JOURNAL,
A Weekly Review of Medicine.

Published by
D. APPLETON & Co.

Edited by
FRANK P. FOSTER, M. D.

NEW YORK, SATURDAY, JUNE 21, 1884.

A PARADISE FOR ABORTIONISTS.

THE June number of the "Columbus Medical Journal" contains a timely and vigorous article exposing the rottenness of the safeguards which the good people of the State of Ohio may be presumed to suppose they have set up against the revolting crime of abortion. It seems that accepted judicial expositions of the statutes of the State are to the effect that criminal abortion is not homicide, even when it results in the death of the woman, and, therefore, that the victim's dying statement is not competent evidence against the accused, since ante-mortem statements are valid evidence only in cases of homicide. Moreover, corroborative testimony will not answer, if we may reason from an instance given by our contemporary, for then the presumption is that the victim really took measures herself which proved effective, and the abortionist was only "called upon to treat her in a purely professional way, but with unfortunate results." Virtually, the law seems to hold criminal abortion as an offense against the fetus only, and, even at that, the prosecution must prove that the fetus was living at the time the act was committed.

The journal alluded to quotes from a judge's charge to illustrate several of the points in question. The charge contained the following passage: "Before you can convict the defendant, the State must satisfy you from the evidence, beyond a reasonable doubt, that the said ——— was a pregnant woman, pregnant with a living fetus or child; that the defendant, ———, did, with intent to procure an abortion in and upon the body of ———, use an instrument to produce a miscarriage, and, in consequence of the use of said instrument, the said ——— either miscarried or died, and that such miscarriage was not necessary to preserve the life of the said ———, and was not advised by two physicians." In other words, criminal abortion is not a punishable offense under the laws of Ohio, unless the product of conception is proved to have been living at the time of the act; the death of the woman counts for nothing.

Such being the facts, it must be conceded that it is well nigh impossible to procure a conviction for abortion in Ohio, but we trust that our contemporary is mistaken in its gloomy forecast that the laws will probably not be changed. "While it would be hardly fair," it says, "to say that public opinion approves of the abortionist, it is certainly speaking within bounds to say that it does not condemn him; the public conscience has ceased to be offended by him. The doctor who, at the request of his patient, uses his knowledge to relieve her of that which she does not desire to retain, is held by the mass of the community as scarcely more blamable than the merchant who, in the routine of business, sells a weapon that afterward becomes an instru-

ment of death." That is the view too apt to be taken by the unthinking everywhere, but we can not believe that the people of Ohio, if once they were made to comprehend the bearing of the facts, would suffer such sophistry to pervade their laws. The "Columbus Medical Journal" can do its community no better service than by instructing it in regard to the heinous nature of criminal abortion. That task accomplished, we may surely trust the virtue of the State to set the statutes right.

MEDICATION OF THE FÆTUS.

THE question of the extent to which drugs administered to the mother during gestation are capable of affecting the fetal organism has often been made the subject of discussion and experiment. What seems to us a most important contribution to our knowledge of the matter has lately been made by Dr. G. Krukenberg, an assistant physician at the gynecological clinic at Bonn, in the form of a communication to the "Centralblatt für Gynäkologie." Substances of ready diffusibility, such as iodide of potassium, have often been found in the contents of the fetal stomach after having been given to pregnant animals, but heretofore the fact has been accounted for on the theory that they first entered the liquor amnii, and gained access to the stomach of the fetus only by the latter's swallowing some of the amniotic fluid. In some instances, however, Dr. Krukenberg has found the reaction of iodide of potassium in the contents of the stomach when neither the liquor amnii nor the fluid between the amnion and the chorion responded to the tests for that substance. He concludes, therefore, that that salt and, presumably, other highly diffusible substances really pass into the fetal circulation from the maternal blood in greater quantities than is commonly supposed, and that they are excreted by the stomach, for in other parts of the fetal organism only traces of them are to be found.

Many of our readers will perhaps remember that, a few years ago, the question of the danger of narcotizing the fetus by the administration of opiates to the mother was debated before the New York Obstetrical Society, and that the discussion fell short of settling the matter. After that, Professor Bollinger gravely advocated the practice of ante-natal vaccination. It will be seen, therefore, that the facility with which medicaments pass from the maternal to the fetal system is noteworthy from a practical point of view.

MINOR PARAGRAPHS.

THE AMERICAN NEUROLOGICAL ASSOCIATION.

ALTHOUGH the programme for the tenth annual meeting is not so extensive as those of some of the national medical societies at their recent meetings, it includes matters of great interest to the profession at large as well as to specialists in neurology. The progress made in that department of medicine of late, indeed, quite justifies the opening remarks made by Dr. Morton on calling the meeting to order. The proceedings at the afternoon session on Wednesday will be found in our society reports, and next week we shall give the concluding portion of the proceedings. The president's address was a scholarly production, eminently appreciative of the bearing of matters that lie at the

base of the science of neurology, and we can not doubt that the election of Professor Wilder as the president for the ensuing year was meant not only as a graceful tribute to a distinguished worker in the field of physiological anatomy, but also as a token of the stress that the association lays on that fundamental branch of investigation.

NEWS ITEMS, ETC.

INFECTIOUS DISEASES IN NEW YORK.—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending June 17, 1884:

DISEASES.	Week ending June 10.		Week ending June 17.	
	Cases.	Deaths.	Cases.	Deaths.
Typhus	7	1	4	0
Typhoid Fever.....	15	3	8	6
Scarlet Fever.....	72	7	65	12
Cerebro-spinal meningitis...	3	3	4	4
Measles.....	148	25	92	14
Diphtheria.....	53	26	37	23

A QUARANTINE ON THE MEXICAN FRONTIER.—A press dispatch announces that quarantine was established on the 15th inst. between Brownsville and Matamoras, both of which places are reported as at present free from yellow fever.

PHYSICAL EDUCATION AT BROWN UNIVERSITY.—At the recent alumni meeting, Dr. W. W. Keen, of Philadelphia, of the class of 1859, presented a resolution looking to the establishment of a gymnasium in connection with the university. The resolution was received with favor, and there is reason to think that the gymnasium will be provided shortly.

THE ADULTERATION OF FOOD AND DRUGS BILL has failed to receive Governor Cleveland's signature.

THE NEW YORK POLYCLINIC.—Dr. George B. Fowler has been elected professor of physiological chemistry. Professor T. Gaillard Thomas has been elected a director, to fill the vacancy occasioned by the death of Dr. J. Marion Sims.

THE AMERICAN PUBLIC HEALTH ASSOCIATION.—At the next annual meeting, to be held in St. Louis, October 14, 15, 16, and 17, 1884, the following topics will be presented for consideration: 1. The hygiene of the habitations of the poor. 2. The hygiene of occupations. 3. School hygiene. 4. The adulteration of food. 5. Water pollution. 6. The disposal of sewage by irrigation and by chemical action. 7. The observable effect upon public health of official sanitary supervision. 8. The work of municipal and State boards of health. From information which we have received, we judge that the meeting will prove of unusual profit.

THE PARIS FACULTY OF MEDICINE.—M. Gosselin, as we learn from the "Union médicale," has withdrawn from his work in the faculty.

AWARDS OF FRENCH PRIZES.—We learn from the "Progrès médical" that the medical prizes of the *Académie des sciences* for 1883 have been awarded as follows: The Monthyon prize is divided between M. Constantin Paul, for his work on the "Diagnosis and Treatment of Diseases of the Heart," M. H. Roger, for his "Clinical Researches on the Diseases of Infancy," and M. E. Vallin, for his "Treatise on Disinfectants and Disinfection." The Bréant prize goes to M. Fauvel, for his "Studies on the Ætiology and Prophylaxis of Cholera." The Godard prize is taken by M. Guelliot, of Reims, for his "Mémoire on the Seminal Vesicles." The Monthyon physiological prize is awarded to M. Paul Regnard, for his "Experimental Researches on the Pathological Variations in Respiratory Combustion." The La-

caze prize goes to Professor Balbiani, but the title of his work is not mentioned.

THE TEACHING OF HYGIENE.—According to the "Medical Times and Gazette," the universities of Prague and Gratz have each established a chair of hygiene, the chair at Prague to be filled by Dr. Soyka, and that at Gratz by Dr. Gruber, both of these gentlemen having been pupils of Pettenkofer's.

FEMALE VACCINATORS, says the "Lancet," have been introduced in Madras, so as to evade the prejudice against native women being treated by medical men.

THE LONDON EPIDEMIC OF SMALL-POX continues to increase. The "Lancet" states that 1,057 persons affected with the disease were under treatment on the last day of May in the various institutions of the Metropolitan Asylums Board.

THE CANADIAN MEDICAL ASSOCIATION.—The "British Medical Journal" learns that Mr. Lawson Tait has accepted an invitation to give an address in abdominal surgery at the next meeting, which is to be held in Montreal on the 25th and 26th of August.

ARMY INTELLIGENCE.—*Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from June 8, 1884, to June 14, 1884:*

THE Army Medical Examining Board, New York city, is dissolved, to take effect June 14, 1884.

BROWN, JOSEPH B., Lieutenant-Colonel and Surgeon. Upon completion of the business of the Army Medical Board, directed to comply with S. O. 44, current series, A. G. O., and return to New York city.

CLEMENTS, BENNETT A., Major and Surgeon. Directed to await orders in New York city.

KIMBALL, JAMES P., Captain and Assistant Surgeon. Granted leave of absence for two months and fourteen days, to take effect June 14, 1884, and ordered to relieve, August 28, 1884, Captain Robert H. White, assistant surgeon, from duty at U. S. Military Academy, West Point, N. Y.

Captain White, on being relieved, ordered to report in person to the commanding general, Department of California, for assignment to duty.

STERNBERG, GEORGE M., Major and Surgeon. Relieved from temporary duty in S. G. O., and ordered to assume the duties of attending surgeon and examiner of recruits, at Baltimore, Md. S. O. 131, A. G. O., June 6, 1884.

FINLEY, J. A., Captain and Assistant Surgeon. Relieved from duty at Fort Stockton, Tex., and assigned to duty as post surgeon, Fort Concho, Tex. Par. 4, S. O. 69, Headquarters Department of Texas, June 2, 1884.

MIDDLETON, PASSMORE, Captain and Assistant Surgeon. Leave of absence extended three months on surgeon's certificate of disability. Par. 3, S. O. 134, A. G. O., June 10, 1884.

BARNETT, RICHARDS, Captain and Assistant Surgeon. Assigned to duty as post surgeon, Mount Vernon Barracks, Ala. Par. 2, S. O. 113, Headquarters Department of the East, June 9, 1884.

GARDNER, EDWIN F., Captain and Assistant Surgeon. Relieved from duty at Fort Walla Walla, Washington Territory, and assigned to duty as post surgeon, Fort Canby, Washington Territory. Par. 1, S. O. 75, Headquarters Department of the Columbia, June 3, 1884.

NAVAL INTELLIGENCE.—*Official List of Changes in the Medical Corps of the Navy during the Week ending June 14, 1884:*

AUSTIN, A. A., Passed Assistant Surgeon. Detached from U. S. S. St. Louis and ordered to Naval Rendezvous, Philadelphia.

EDGAR, J. M., Passed Assistant Surgeon. Detached from U. S. S. Wabash and ordered to U. S. S. Nantucket.

BALDWIN, L. B., Passed Assistant Surgeon. Ordered to U. S. S. Wabash.

WHITAKER, H. W., Assistant Surgeon. Detached from Naval Rendezvous, Philadelphia, and ordered for examination preliminary to promotion.

HESLER, F. A., Assistant Surgeon. Ordered to U. S. S. Minnesota.

MEANS, V. C. B., Assistant Surgeon. Ordered to U. S. S. Vermont.

BROWNE, J. M., Medical Director. To attend the International Health Exhibition at Liverpool, England, and delegate to International Medical Congress at Copenhagen, per steamer of July 2d.

TRYON, I. R., Surgeon. To same duty with Medical Director Browne, and, on completion of this duty, to report for duty on U. S. S. Quinnebaug.

HUGG, J., Surgeon. Detached from U. S. S. Quinnebaug; on reporting of relief, to return home and report arrival.

SOCIETY MEETINGS FOR THE COMING WEEK.—*Tuesday, June 24th*: Jersey City Pathological Society; Medical Societies of the Counties of Essex, Lewis (annual), and Washington, N. Y.

Wednesday, June 25th: New York Pathological Society; American Microscopical Society of the City of New York; Auburn, N. Y., City Medical Association.

Thursday, June 26th: New York Academy of Medicine (Section in Obstetrics); Harlem Medical Association (private).

Friday, June 27th: New York Clinical Society (private); New York Society of German Physicians (private).

Saturday, June 28th: New York Medical and Surgical Society (private).

OBITUARY NOTES.

DR. JOHN G. ADAMS.—Shortly before the time for this issue of the journal to go to press, a cable dispatch was received at the Park Avenue Hotel, where Dr. Adams had resided of late, stating that he died in Liverpool on Thursday morning, but giving no information as to the circumstances of his death. For a number of years past Dr. Adams had been in infirm health, but we are not aware that there was anything known to his friends about his physical condition, prior to his recent departure for England, to lead to anxiety.

Dr. Adams was born in New York, August 12, 1807. He was educated at Yale College, and received his medical degree from the College of Physicians and Surgeons in the year 1830. For many years past he has not been a practitioner, although he has constantly shown his interest in medical matters, particularly those relating to the welfare of the profession as an organized body; indeed, so recently as last February, he represented the Academy of Medicine at the annual meeting of the Medical Society of the State of New York. He was a man of pronounced convictions and uncompromising in their enforcement, but of a kindly nature, so that he was esteemed by all who knew him. At the time of his death he was the corresponding secretary of the Academy of Medicine, a member of the board of managers, and a benefactor of the Society for the Relief of the Widows and Orphans of Medical Men, a trustee of the College of Physicians and Surgeons, and a member of the Medical Society of the County of New York, the New York Medical and Surgical Society, and the New York Physicians' Mutual Aid Association.

DR. A. BLONDEAU, OF PARIS.—The "Progrès médical" announces that on Thursday, the 29th ult., the secretary of its

editorial staff, Dr. Blondeau, died in consequence of gout with many and grave complications. The journal in question speaks feelingly of its loss, and of that of its readers.

Letters to the Editor.

RODGERS'S OPERATION FOR WEBBED FINGERS.

NEW YORK, June 16, 1884.

To the Editor of the New York Medical Journal:

SIR: In your journal for June 14, 1884, I notice an editorial entitled "Rodgers's Operation for Webbed Fingers," claiming for the late Dr. J. Kearny Rodgers priority in the suggestion of the ingenious plastic operation for the relief of this deformity commonly attributed to the Belgian surgeon Didot.

This claim is made on the strength of a statement made by Dr. A. C. Post, of this city, in his paper on Ectrodactylism and Syndactylism, published in the same issue of your journal.

At the time referred to by Dr. Post (1846) I was an *interne* in the New York Hospital, Broadway and Pearl Street. I remember distinctly Dr. Post's case, also the case, to which he refers, in which one of his colleagues in the New York Hospital undertook the performance of Dr. Rodgers's operation, but made the singular mistake mentioned by Dr. Post.

The matter was much talked about at the time, and I heard Dr. Rodgers describe his method. There was no doubt among surgeons frequenting the hospital that the credit of devising this ingenious operation belonged to Dr. J. Kearny Rodgers.

Yours very truly,

GEORGE A. PETERS.

Proceedings of Societies.

AMERICAN NEUROLOGICAL ASSOCIATION.

Tenth Annual Meeting, held in New York, Wednesday, Thursday, and Friday, June 18, 19, and 20, 1884.

Wednesday's Proceedings.

THE President, Dr. EDES, being absent, Dr. W. J. MORTON called the meeting to order, and remarked that, looking over the year's work, it could justly be said that the association had not taken a backward step.

More than the usual annual accession of active members had joined, or were about to join, their ranks. The published report of the proceedings of last year had been prepared with great care, and had been published, entire or in part, in many languages. A glance backward at the cause they represented was full of suggestion, guidance, and assurance. Ten years ago, when the association was first organized, no one would have ventured to say that neurological specialism would assume the stalwart proportions that it to-day possessed. In the marvelous onward stride of medical science, division of labor had become a necessity. The growth of neuro-pathology had been rapid and strong. General medicine and surgery were under constant obligation to the neuro-pathologist. Neurological nomenclature, formerly confined to the few, was now becoming the medical vernacular.

"It now becomes my agreeable duty," continued Dr. Morton, "to introduce the president-elect, Dr. Isaac Ott, of Easton, Pa. No words are needed from me. His works have already spoken for him."

THE PRESIDENT'S ADDRESS.—After thanking the association for the honor conferred upon him, Dr. OTT directed attention to the paths of the various fibers in the spinal cord. About seventy years ago Charles Bell announced that the anterior roots of the spinal cord were motor and that the posterior roots were sensory. The physiology of the cord as taught to-day was mainly due to improvements in the technique of minute anatomical research. Longuet, in 1840, made numerous experiments, and arrived at the conclusion that the anterior columns of the spinal cord were motor and the posterior sensory. Brown-Séquard also made an extended series of experiments, and believed that the transmission of sensory impressions in the spinal cord took place chiefly through the gray matter and partly through the anterior column; that the voluntary impressions in the upper part of the cervical cord were in the lateral columns and in the gray matter between them and the anterior columns; that no tactile sensations ascended the posterior columns to the brain. As to the kind of sensations conveyed upward, he made at least seven. These views had since been somewhat modified by his studies of inhibition. Professor Schiff thought the posterior columns conducted tactile impressions, that the gray matter conducted in all directions afferent impulses which gave rise to affections of general sensibility and such afferent impulses as were concerned in reflex action. Further views of these authors were presented for the purpose of showing that the facts put forth were greatly in need of correction. After reviewing the opinions of Ludwig, Finck, and others, upon the subject, and referring to his own experiments, Dr. Ott arrived at the conclusion that the lateral columns conducted sensory and motor impulses; that the gray matter did not directly participate; that the anterior columns conducted impulses of voluntary motion; that tactile impulses also passed up the posterior and lateral columns; and that different nerve-tracts crossed over one another.

REPORTS OF OFFICERS.—The COUNCIL, the SECRETARY, and the TREASURER then submitted their reports, after which the nomination of candidates for membership and for office was in order.

ELECTION OF OFFICERS.—Dr. B. G. WILDER, of Ithaca, N. Y., and Dr. C. K. MILLS, of Philadelphia, were nominated for the presidency, and on the first ballot each received five votes. Dr. Wilder was elected on the second ballot. Dr. LEONARD WEBER, of New York, was elected vice-president, and Dr. G. M. HAMMOND, of New York, secretary. Dr. W. R. BIRDSALL and Dr. W. J. MORTON, of New York, were elected members of the council.

Dr. WILDER then exhibited PREPARATIONS ILLUSTRATING (A) THE EXISTENCE AND CIRCUMSCRIPTION OF THE PORTE (FORAMINA MONROI) IN THE ADULT HUMAN BRAIN; (B) THE PRESENCE OF THE CRISTA FORNICIS IN FETAL AND NEW-BORN HUMAN BRAINS; (C) TWO ADDITIONAL CASES OF ABSENCE OF THE CALLOSUM IN THE DOMESTIC CAT; (D) THE COVERING OF THE CEREBELLUM BY THE CEREBRUM IN A YOUNG CHIMPANZEE WHOSE BRAIN HAD BEEN HARDENED WITHIN THE SKULL.

Dr. R. W. AMIDON presented a human brain, in which there was ABSENCE OF THE CALLOSUM, and said he would read the history subsequently.

Dr. E. C. SPITZKA said it was an error to suppose that a preponderance of the cerebrum over the cerebellum was *per se* an indication of high development. On the contrary, the cerebellum being midway, so to say, of fibers to be finally transported to the cerebrum, and forming a dépôt for the higher centers, it stood to reason that, if any relation existed between them, the two must progress evenly. As we proceeded from a lower to a higher form of being, the cerebrum and cerebellum became more intricate.

Among the anthropoid apes, the lesser overlapping of the cerebrum was really an indication of higher development on the part of the chimpanzee.

Dr. WILDER said he had presented the specimens to illustrate the importance of making anatomical preparations in a manner that would not misrepresent nature, thus avoiding a great deal of unnecessary discussion, false conclusions, and the use of printer's ink.

Dr. SPITZKA said, further, that Benedikt, of Vienna, had made the statement that in criminals the cerebrum did not overlap the cerebellum, but it had been shown in a discussion at a society meeting that the projection of the cerebellum in the cases which he had examined was due to the position in which the brain lay; and this was another proof of the advantage of Dr. Wilder's method of hardening preparations.

(To be concluded.)

CHICAGO MEDICAL SOCIETY.

Meeting of May 19, 1884.

A UNILOCULAR OVARIAN CYST WEIGHING TWENTY-FOUR POUNDS.—Dr. CHARLES T. PARKES showed a specimen, and related the case. The cyst was perfect, and had been removed four days before from a girl nineteen years old. It had probably been developing for three years, and for two years and a half the girl had been treated for various disorders, such as dropsy and the like. Six months ago she consulted Dr. Parkes, who diagnosed an ovarian cyst. It had gradually increased in size until the abdomen had attained the circumference of forty-four inches. There had been no symptoms except those arising from its large size, and the girl was in good health. It did not appear to be compound, and it was judged that but few adhesions would be met with. [When the specimen was inflated with air there were no corrugations, and it was considered one of the most beautifully developed unilocular ovarian cysts ever seen at the society.] In the operation for its removal an incision three inches and a half in length was made. The pedicle was found to be very broad, as usual with cysts of this sort; it was secured with a double ligature. No coils of intestine were adherent to the cyst, and but a single shred of omentum was involved. After the operation the temperature did not rise above 99.5° F. The pulse went up to 100, but was now ranging in the nineties, and convalescence was predicted. The interest of the specimen lay chiefly in its perfection, as shown by its rotundity when inflated. The sac weighed one pound, and the contents twenty-three pounds.

A UTERINE MYOMA WEIGHING THIRTY-FIVE POUNDS; ABDOMINAL MYOMOTOMY.—The second specimen was shown by Dr. E. C. DUDLEY. The patient was a Norwegian woman, forty-eight years old, a domestic, who was unmarried and had never been pregnant. The operation for the removal of the tumor was done on the 17th of March. Two years ago last autumn the woman ceased to menstruate. The tumor had been developing for a number of years, and all the surgeons whom she had consulted during the past three or four years had stated that any attempt at its removal would destroy her life. On examining the tumor, Dr. Dudley supposed it to be a fibroid with extensive adhesions. It had developed in the left side of the pelvis. There was no tympanites on that side, but a line of resonance extended for eight or nine inches over the transverse colon. The cervix could scarcely be reached by the vagina, and no outline of its vaginal portion could be determined. The tumor was very hard, and it was judged to be of unusual size. His prognosis was that without operation it would prove fatal, and that with an operation there was but little hope of recovery. The patient sought Dr. Dudley's opinion as to the chances

for her from an operation on several occasions, at intervals of a few days, and was told that the operation was not necessarily fatal. Her appetite was greatly impaired, her stomach rejected almost all kinds of food, she had become very anæmic, and her emaciation was such that she presented almost a cadaveric appearance. The operation was performed with the assistance of Dr. R. N. Isham, Dr. C. Fenger, Dr. W. W. Taggard, Dr. W. P. Verity, Dr. George Isham, and a student. For two days before, the patient had been put in as good a condition as possible, the attentions given her including two administrations of the Turkish bath. All the furniture of the room, including carpets, curtains, etc., were removed and thoroughly disinfected, and for twenty-four hours her bed-room was subjected to the action of the fumes of sulphur. Her abdomen was washed with a weak solution of corrosive sublimate; the hair was shaved from the pubes and from about the vulva—in short, every possible lodging-place for infection was carefully cleansed. Like precautions were taken with her clothing, her bed-linen, etc. The ligatures to be used were boiled for ten minutes in a ninety-five-per-cent. solution of carbolic acid, and for half an hour in a five-per-cent. solution; all the instruments to be used were subjected to the influence of flame, and then carbolized; and the hands of all who were to be present were washed in carbolized water. When the patient had been anesthetized with ether, an incision was made, extending from the umbilicus upward to within two inches of the ensiform cartilage, eighteen inches in length. This was done for fear of opening into the bladder by cutting downward, for the tumor had drawn the bladder up to the umbilicus, being adherent to it by its anterior surface. The urachus was opened, and a spurt of urine followed. A large bundle of vessels, looking like intestine, was severed, and it was with some difficulty that these vessels were tied. The weighty mass was now exposed, springing from the left side of the uterus and involving the broad ligament. The tumor measured at least a foot in each of its diameters. The mass was firmly adherent to the peritonæum posteriorly, but the bladder was peeled away from it easily. An hour and a half had been consumed before the pedicle was secured, which was done with an elastic ligature, a solid rubber cord a quarter of an inch in thickness, wound four times around the pedicle, before the tumor was severed from the uterus. Another tumor, of the size and shape of a foetal head, was then discovered, filling the true pelvis, and it seemed wonderful that the functions of the rectum and bladder had not been more interfered with. The lesser tumor sprang from the posterior wall of the uterus, and its pedicle, which was as large as a man's fist, was secured by precisely the same kind of ligature as had been used on the larger one. The large tumor especially was exceedingly vascular. Much time was lost in applying Esmarch's bandage, but it slipped off, and its use had to be abandoned. The patient's pulse had become very feeble—indeed, she seemed more dead than alive. She was placed in bed, with two drainage-tubes in the wound, and the pedicle secured externally with a clamp. The minor details connected with the closure of the wound were carefully attended to.

From the first day to the eighth she was conscious, flatus passed downward, her temperature ranged between 98° and 101°, and her pulse between 100 and 120. On the ninth day her temperature rose to 102·8° in the morning, and to 103° in the evening. On the eleventh and twelfth days the temperature went up to 104·5°, with aggravation of her condition otherwise. It was thought that pus was forming in the lower part of the abdomen, and, with the assistance of Dr. R. Tilley and Dr. Fenger, this cavity was opened through the vagina. At least half a pint of foetid matter escaped, and a drainage-tube was passed in through Douglas's *cul-de-sac*. The abscess, which

had formed below the pelvic organs, was carefully washed out with a warm, weak solution of carbolic acid, and within two days a large amount of pus was discharged and her temperature had fallen two or three degrees. In a few days it rose again to 104·5°, and the pulse to between 135 and 140, and she had hectic chills. A counter-opening was made, and the symptoms again became ameliorated, the pulse keeping about even pace with the temperature and respiration until the twenty-seventh day, when the drainage-tube passing through the *cul-de-sac* was removed, together with the smaller-sized ligature. This procedure was followed by a slight rise of temperature. On the thirty-seventh day the large double ligature, consisting of the rubber cord, was removed, and a considerable sloughy mass came with it. After four days more the opening into the vagina closed spontaneously. On the sixtieth day the temperature rose to 101°, or perhaps a little higher, and the cause assigned for it was that she had exposed herself at an open window the day before. The following day the temperature rose to 102°, and there was considerable fever, but, under the use of suitable measures, these symptoms had all improved again by the evening of the sixty-third day, and there could now be no doubt of her final recovery. Throughout the entire treatment of the wound, it was dressed with iodoform by insufflation, and the drainage-tubes were at all times carbolized. The patient was now in excellent condition.

Referring to the points of interest in the case, and those of difficulty in such operations, Dr. Dudley laid stress upon the advantage of the double rubber ligature over silver and silk.

Dr. PARKES referred to the difficulties of diagnosis presented by these tumors. Multiple fibromas, he said, were difficult of removal. He had done the operation in three instances, and all the patients had died, but yet the prognosis was as good as it was a few years ago after ovariectomy, and the operation was fully justifiable. He favored the extra-peritoneal method of dealing with the pedicle, as had been adopted in Dr. Dudley's case.

Dr. J. R. FLOOD spoke of this particular operation as a triumph of surgery, considering the magnitude of the specimen.

Dr. G. H. RANDELL asked if removal of the uterus would have been practicable in this case.

Dr. R. TILLEY corroborated some of the particulars alluded to by Dr. Dudley, and in particular spoke of the amount of pus that escaped when the opening was made in Douglas's *cul-de-sac*.

Dr. L. H. MONTGOMERY inquired of the operator how much of the incision yet remained open. He understood, of course, that its great length was made necessary by the solid character of the tumor, and he presumed that it did not contract after the operation, as the incision usually did after the removal of an ovarian cyst.

Dr. J. H. EYERIDGE asked what the depth of the uterus was before the operation.

Dr. DUDLEY said that the depth of the uterus before the operation was very nearly normal, only about three inches. The incision had now closed entirely, except for an opening only large enough to admit the tip of his little finger; as suggested by Dr. Montgomery, it had not contracted after the operation as it usually did after ovariectomy. It would not have been practicable to remove the uterus, but such a procedure would have increased the danger of the operation. The extra-peritoneal treatment of the pedicle was sometimes quite impossible to carry out. In his case, Nature had insisted on changing the intra-peritoneal to the extra-peritoneal treatment, and had thus saved the patient. During a part of the time consumed by the operation, it had been necessary to insert disinfected sponges into the abdominal cavity; they were soaked in a weak solution

of carbolic acid—perhaps of the strength of one to twenty thousand, which was said to be strong enough to destroy germs.

LISTON H. MONTGOMERY, M. D., *Secretary.*

NEW YORK PATHOLOGICAL SOCIETY.

Meeting of June 11, 1884.

Dr. R. W. AMIDON, Chairman for the evening.

FIBROUS TUMOR OF THE BREAST; TUMOR OF THE PENIS; LIPOMA OF THE SHOULDER.—Dr. WACKERHAGEN presented three specimens, which were referred to the microscopical committee. The tumor of the breast had begun to develop twenty-five years before, as a small lump, and during the last two years had become painful. It weighed nine ounces. A tumor weighing two ounces was removed from the axilla. An imperfect examination pointed to a fibrous, not a cancerous, growth. The wound healed entirely under bichloride and iodoform dressing by the eleventh day, when the dressing was removed for the first time.

TUBERCULAR PERITONITIS IN A CHILD.—Dr. NORTHRUP presented the intestines of a child which died at the fourth year of age, of tubercular peritonitis. It was brought to the New York Foundling Asylum in February, with ascites. It had been out, attended by a nurse, and was reported as in good condition. While it was in the hospital the feel of the abdomen became more or less boggy, and finally the fluid ceased to change position when the child was turned from side to side. There were no symptoms except those of bronchitis and occasional attacks of constipation. Death took place from exhaustion. At the autopsy, the abdominal wall was found closely adherent to the mass within. The coils of intestine, both large and small, were glued together, constituting one mass with the liver, spleen, and stomach. The liver, spleen, and kidneys contained a few miliary tubercles. In the lungs the tubercles were scattered throughout, and there was diffuse pneumonia with oedema. The brain was not examined. One ureter was much dilated, due probably to a constriction arising from adhesion. Ulcers in the intestine had perforated the gut. The peritonæum contained large round tubercles throughout. Dr. Northrup remarked that this was the only case of the kind which he had seen in a child, although he had examined over two hundred children which had died of tuberculosis. Death from tubercular peritonitis might not be very uncommon in the adult, however.

Dr. PEABODY said he had not seen the condition in children. He thought it was not very uncommon in the adult.

Dr. PETERS had seen tubercular peritonitis in two children in the same family, one being between two and three, and the other between four and five years old. There were at first only symptoms referable to the bladder, and afterward those pointing to the brain. In these cases, also, the tubercles were not limited to the peritonæum, but were found in the liver, spleen, and kidneys as well. The brain was not examined. There was no family history of tubercle.

Dr. FERGUSON said that some time ago he made an autopsy in a case in which certain physicians had made a diagnosis of an ovarian tumor, there being an abdominal tumor, and he found, on opening the abdomen, that there had been a perforation of the intestine, as in Dr. Northrup's case, and the escaped contents had become limited by inflammatory material and presented the appearance of a tumor.

TUBERCULAR MENINGITIS IN A CHILD.—Dr. KNIGHT presented a part of the brain of a child which died of tubercular meningitis at one year of age. The case was somewhat interesting on account of a family history of syphilis misleading the physician to make a diagnosis of syphilitic meningitis. The child had been sick about five days when Dr. Knight was called. On the sixth day the patient was apparently unconscious, the

head rolling from side to side, with occasional muscular twitchings, the pulse being regular, and the temperature not elevated or but slightly so. No nourishment was taken. The second day after he saw her she was lying on the left side, apparently asleep, the left arm and leg being drawn up and down constantly. The right side was motionless. The movement of the left arm and leg continued constantly day and night. There was some movement of the jaw on his visit on the third day. There were occasional twitchings of the lids on the sixth day, and the eyeballs were constantly moving. The left arm became rigid on the sixth day. There was a violent spasm of the right side on the seventh day, and three hours later the child died. The temperature did not go above 101° F. At the autopsy, tubercles and a translucent membrane were found covering a considerable portion of the base of the brain, including the cerebellum, the optic chiasm, and the pons. The father had contracted syphilis about five years and a half before the birth of the child, and about a year later the mother had become infected. During the first year of the mother's disease a child was born which presented the signs of syphilis. The child from which the specimen was taken was born during the fifth year of the mother's infection. It had no lesions at birth, nor afterward. Dr. Amidon, who made the microscopical examination, had first supposed there was syphilitic lesion, but it proved to be, apparently, purely tubercular.

The CHAIRMAN remarked that in certain cases, as in this one, we found the gross lesions more like those of syphilis than those of tuberculosis, while the microscopical examination discredited the theory of syphilis.

Dr. NORTHRUP thought the symptoms pointed pretty clearly to tubercular meningitis.

Dr. PEABODY said a woman was admitted to the New York Hospital suffering from symptoms of meningitis, from which she died. At the autopsy he found a condition of things very similar to that which Dr. Knight had described as covering a part of the base of the brain, and extending down on the anterior surface of the spinal cord—a thick, gelatinous looking substance, from an eighth to a sixteenth of an inch in thickness, quite clear, and containing no tubercles. There was perivascularitis, and in some places there was endarteritis obliterans, which led him to believe it was syphilitic. There were no tubercles at any place. Possibly in Dr. Knight's case there were both tuberculosis and syphilis.

Dr. NORTHRUP thought that, as a rule, in well-developed tubercular meningitis there was a gelatinous layer at the base of the brain, which was apt to be of a greenish color.

Dr. VAN GIESON thought twelve days rather a short course for tubercular meningitis. Cases in which there was a large amount of congestion were more likely to be attended by the gelatinous effusion. With regard to whether or not syphilis might have been an ætiological factor in Dr. Knight's case, he thought that in children who died from a syphilitic lesion of the brain there were almost always previous skin lesions. The low temperature in this case was not extraordinary. He had attended a case of tubercular meningitis which terminated in death, the temperature at no time going above 100° F., although it was taken frequently and with different reliable thermometers. He replied to a question by the chairman that, if there were a sudden rise of temperature, it was likely to be pre-agonistic. This, however, by no means always occurred. The symptoms presented in the case narrated by Dr. Knight were not unusual.

The CHAIRMAN thought there was always a pre-agonistic rise of temperature in tubercular meningitis. He then presented microscopical specimens illustrative of the disease as it occurred in a child five years and a half old. There was a marked

family history of tuberculosis. The child had always been well, but was sensitive to cold. Three weeks before the fatal illness it began to cut its back teeth, and was very irritable, and then began to act in a manner pointing to meningitis—not wishing to be disturbed, preferring a darkened room, and appearing irritable. At seven o'clock of the morning of the last day of life the patient was for the first time seized with a general convulsion. It had been sleeping well during the night, and awoke conscious. It lost consciousness, and the eyes remained open and fixed. It lay bathed in a warm perspiration, the temperature being 105°. Death took place at noon. At the autopsy the base of the brain was found studded with miliary tubercles. The other viscera were not examined.

Dr. PETERS remarked that he had found the primary symptoms more variable in tubercular meningitis than in almost any other disease. The manifestations would correspond to the order in which the roots of the nerves were invaded at the base of the brain. He knew of no affection in which it was more difficult to make a definite diagnosis during the first four or five days than in tubercular meningitis.

The CHAIRMAN regarded the premonitory stage of irritability, inability or disinclination to talk, dread of being disturbed, and desire to rest quiet in a dark room, as almost pathognomonic of the onset of the disease.

Dr. L. LEWIS SMITH, who had just arrived, being asked his experience as to the course of the temperature in these cases, said it had varied in height according to the extent of the meningeal inflammation. If the amount of inflammation excited by the tubercles was moderate, the febrile movement would be mild. He had been interested in Dr. Peters's remark as to the difficulty of making a diagnosis early in the course of the disease. He had frequently been called to see cases in which the physician had previously dignosticated remittent fever.

ULCERATIVE ENDOCARDITIS; ANOMALY OF THE LIVER.—Dr. FERGUSON presented the liver and heart of a boy who died at the fourteenth year of age, having for two months before admission to the hospital complained of shortness of breath, weakness, and loss of appetite. On admission, he was fairly nourished, the face looked puffy, he was anæmic and cachectic, and suffered from dyspnoea, the breathing being principally diaphragmatic. The pericardial area was increased, and a harsh cardiac murmur was present. He died quietly two days after admission. The cavities of the heart were dilated. One of the aortic cusps was nearly destroyed, and just above it was a small, smooth opening in the aortic wall, which communicated with the interventricular septum. The left lobe of the liver was only rudimentary. The right was roundish in form, and on its surface there were a few small nodules. The gall-bladder was divided by a septum into two lobes. This was the first time Dr. Ferguson had seen this anomaly.

FIBROUS AND FATTY DEGENERATION OF THE HEART WALLS.—Dr. PEABODY presented the heart of a woman, fifty-six years old, who died in the New York Hospital after having been under observation for about two weeks. The history was quite meager. She was the mother of seven children, and had been in comparatively good health until four months before admission. Twelve years ago she had suffered from cardiac palpitation. On admission, she was suffering from dyspnoea, there was œdema of the lower extremity and of the lower half of the abdominal wall, and there was also marked ascites. When she first entered, she was passing more urine than normal, but the amount gradually diminished to twelve ounces daily, and even less. It contained albumin, and hyaline and granular casts. The specific gravity was in general low. The liver was displaced downward and gave rise to difficulty in diagnosis. At the autopsy, the kidneys were found to be the seat of parenchymatous and inter-

stitial nephritis. The heart was both dilated and hypertrophied. The point of greatest interest was the presence of a large amount of fibrous tissue in the wall of the left ventricle, especially at its apex, where it was very thin. The microscopical examination showed fatty degeneration of the muscular wall in the immediate neighborhood of the white fibrous tissue, while, just beyond, the wall was normal. The endocardium was everywhere thickened. There was an abundant atheromatous deposit in the aorta, surrounding the coronary arteries, and in the mitral valve. The valves were competent. There was a slight degree of cirrhosis of the liver, with marked evidence of tight lacing. The peritoneal cavity contained 2,500 c. cm. of fluid. Dr. Peabody said that, clinically, this form of cardiac hypertrophy without valvular lesion gave the patient greater distress than any other. Here there was no valvular lesion, no murmur, no apparent interference with the function of the heart, but there was marked hypertrophy of the ventricular wall, which subsequently gave place to dilatation. In reply to a question by Dr. Van Gieson, whether angina pectoris was present, Dr. Peabody said it was not, but he presumed that was to be accounted for by the fact that the occlusion of the coronary arteries had not yet reached quite a sufficient degree. He thought that any condition causing their occlusion might give rise to the symptom.

Dr. PETERS referred to two cases in which patients suffering from angina pectoris died suddenly, and obstruction of the coronary artery was found.

THE MASSACHUSETTS MEDICAL SOCIETY.

One Hundred and Third Annual Meeting, held in Boston, June 10 and 11, 1884.

The President, Dr. ALFRED HOSMER, of Watertown, in the chair.

Wednesday's Proceedings.—(Concluded from p. 671.)

SANITARY FOREST CULTURE.—Dr. J. F. A. ADAMS, of Pittsfield, read a paper in which he spoke of the great destruction of forests in this country, and alluded to the interest in forest culture that had been created during the past few years by various societies which had been organized to promote and protect this interest. Forests acted beneficially, and their destruction should be resisted upon sanitary grounds. They acted by, *first*, regulating the streams; *second*, modifying the climate; *third*, acting as a protection from malarial influences. The change in the character of the productiveness of the soil in the south of France was alluded to. The effect of forests on the water-supply was shown, for, in places where there had been a destruction of trees and a second growth had been allowed to come up, the springs had become refilled. As an example of this, Palestine was mentioned, where, by the culture of new groves of the oak and the olive, the springs, which had for a long time been dry, were now filling up again. He also told of the experiment by which the planting of twenty millions of trees had doubled the water-supply of the locality. Yet, in contradistinction to this, he said that in Marietta, where a record had been kept since 1817, no perceptible change in the water-supply had been noticed, though the forest lands had been decreased by thirty per cent.

Forests modified the climate by sheltering us from the force of the wind; they also cooled the air in summer, and warmed it in winter. The statement was made that in well-wooded countries thunder-storms were not so severe as in other places.

Under the third head he said that trees served as a protection from malarial diseases. Acting in a mechanical way, the experiments of Professor Tyndall tended to show that this was the most likely way for them to have any effect.

It was a well-known fact in malarious countries belts of trees around a house acted as a protection. The freedom of the dismal swamp from malaria was attributed to the large growth of cypress-trees there. To strengthen this idea, it was said that malaria was not known in Rome till after the trees on the marshes had been felled, and the same might be said in a less degree of certain parts of France and Spain, and trees were now planted to stop this influence.

In order to insure the protection of forests and prevent this wholesale destruction we should

1. Educate the people and instruct them as to the dangers to be expected from such a course.

2. Look to the enactment of laws for the protection of forests as they now were.

3. Establish schools of forestry in the various agricultural or similar institutions.

The reader stated that eleven States had laws regulating the depletion of forests, and in seven more similar laws were likely to be enacted.

One great reason why the public were not alive to the issue was that the benefits were not sufficiently local to demand earnest work.

Often the stream that furnished the water-supply to a town had its source in another town, county, or State; and the same reason applied to manufacturers, and influenced them in a like manner. The true way was to have towns or corporations take the matter in charge, and have the State control and regulate the sale of lumber from its lands.

In western Massachusetts it was a well-recognized fact that some of the farm-lands formerly the best had been rendered barren by the wholesale destruction of the trees. The soil, becoming dry and loose around the roots, was washed away by the rains, and the rocks below were all that was left.

If the planting of trees was resorted to, the soil would undoubtedly become as fertile as before.

WEIGHT AS AN INDICATION OF THE CHARACTER OF RISKS FOR LIFE INSURANCE.—Dr. JOEL SEAVENS, of Roxbury, read a paper with this title.

From among 974 deaths that had been recorded in the past six years in a beneficiary society, the reader had collected all which had occurred of persons who at their admission weighed 15 per cent. or more less than the normal standard, 138 in all, and showed in tabular form a list of them, giving their age, height, weight, the length of time they had lived after being examined for admission, and the cause of death. From this it appeared that there was a large mortality among them, due in great measure to tuberculosis and other wasting diseases; that this tendency was not manifested simply among those who were more than 20 per cent. lighter than the standard, but was present also in those not more than 15 per cent. below that line.

It was stated that in companies and societies which insured lives it was generally assumed that a variation of 20 per cent. might safely be allowed without danger of incurring loss, but the reader was satisfied that, where a deficiency of even 10 or 15 per cent. existed, the risk must be looked upon as hazardous, or at least should be thoroughly scrutinized and tested to prevent the possibility that this deficiency in weight might be found to be only a symptom of constitutional disease, or an evidence of some pre-tuberculous condition.

A table was next presented of 122 from out the same 974 deceased members who at joining were 15 per cent. or more above the standard weight, and the causes of death among them were also shown. It was pointed out that this class was made up of much older men, who died of a very different group of diseases from those of which the class deficient in weight had been found to die of; that with those who were but little above

the standard (15 to 20 per cent.), the results were much more favorable than with the light weights in the same range, that it was not till the excess became 20 to 25 per cent. that the mortality became large, and that even with those above this rate was no such evident result of fatty degeneration or general cachexia as might have been anticipated. Deaths from cerebral and cardiac changes were prominent, as were also sudden deaths, but not so markedly so as we were generally taught to expect. In conclusion, the reader believed that men, especially young men, who were deficient in weight, even when the deficiency was not more than 15 per cent., were more hazardous risks than those whose weights were 20 to 25 per cent. above the usual standard, especially because of the great liability of the former to become phthisical, a tendency which need not be feared among the corpulent. Care, however, should be taken with the latter to see that the heart and kidneys were in a healthy condition, and that there was no hereditary tendency to cerebral disease.

At twelve o'clock the ANNUAL DISCOURSE was given by Dr. JOHN CROWELL. Referring briefly to the material prosperity of the country, he spoke enthusiastically of the recent progress in the medical profession, the investigations of observers with the microscope, and the benefit derived from such knowledge. He spoke earnestly of the bad sanitary condition of most dwelling-houses, the plumbing in few being what it should be. The houses in the country to which invalids were sent were frequently in the most wretched sanitary condition. The need of preparing palatable, nutritious food was mentioned, and the conduct of the sick-room was alluded to, the value of a trained nurse being emphasized. The attitude of this branch of the profession toward the other schools was considered. The speaker referred also to the danger of public funerals in the case of deaths resulting from contagious diseases, to the subject of vaccination, and to the laws regulating the practice of medicine.

At the close of the address a vote of thanks of the society to the orator was passed. The Chair then introduced the newly elected president of the Society, Dr. C. D. HOMANS.

At one o'clock the ANNUAL DINNER was served in the Skating Rink, Clarendon Street, about 750 members and invited guests being present.

Dr. GEORGE B. SHATTUCK, of Boston, was the anniversary chairman.

After-dinner speeches were made by Dr. CHARLES HOMANS, Dr. ALFRED HOMER, GOVERNOR ROBINSON, the Rev. Dr. COURTNEY, Dr. JOHN CROWELL, the Hon. W. A. FIELD, and others.

NEW YORK OBSTETRICAL SOCIETY.

A STATED meeting was held February 5, 1884, W. M. POLE, M. D., President, in the chair.

MISSED ABORTION; SOLEROISIS OF THE PLACENTA.—Dr. H. J. GARRIGUES presented a specimen, accompanied by a written history. [See p. 690.]

TWO CASES OF OÖPHORECTOMY.—In the absence of the author, Dr. B. F. DAWSON, Dr. C. C. Lee had been requested to read for him the histories of two cases of oöphorectomy, and to present the specimens:

CASE I.—Mrs. F., aged thirty, for two years a widow, with no children, had had one miscarriage at the third month, occurring after a strain, about two years ago. She had been well up to that time, but soon afterward began to suffer from severe neuralgic pains in the pelvis and from dysmenorrhœa. These symptoms gradually increased in severity until she consulted Dr. Dawson in December, 1883. He found the right ovary enlarged, tender, and prolapsed, and apparently fixed in the cul-de-sac. Oöphorectomy was advised, and was performed on January 19, 1884. An incision two inches and a half long was

made, and the right ovary was brought into the wound with considerable difficulty. The tube and the ovary were ligated, and removed with the cautery. Some hæmorrhage from a small rent in the pedicle subsequently rendered enlargement of the incision necessary, when the pedicle was again ligated and cauterized. The left ovary and tube, with a small cyst of the broad ligament, were found directly under the abdominal wall, and were removed without difficulty. The patient made a very satisfactory recovery. The highest temperature—103° F.—occurred on the third day, and readily yielded to the abdominal coil. Particular attention was paid to the "peritoneal toilette."

CASE II.—Mrs. E. T., aged thirty-seven, married eight years, was the mother of two children, the last one born five months since. The labor was complicated by post-partum hæmorrhage. Dr. W. A. Hammond and Dr. C. H. Brown were consulted by her husband, with the history that she had attempted suicide eight years before, and that symptoms of melancholia had developed. When she was seen, her gait was stooping; the brows were strongly wrinkled; she had no hallucinations. She cried a great deal, would not answer questions, but often complained of pains in the head, breast, and pelvis. She was referred to Dr. Dawson, who discovered ovarian tenderness and prolapse of the right ovary into the *cul-de-sac*, and advised oöphorectomy, which was performed on January 21, 1884. An incision two inches and a half in length was made, and the ovaries were removed without difficulty. Recovery was rapid. At the present time the mental condition was improved; she cried less, and the brow was smooth.

Both patients were operated upon at their houses. The spray was used in the room, but not over the abdomen. As soon as the peritonæum was opened, the edges of the wound were protected by carbolyzed napkins, to prevent any access of blood to the peritoneal cavity, and extreme cleanliness in every detail was practiced.

Dr. LEE remarked that the condition which was found to exist in the first case, and which looked very much like a hydro-salpinx, certainly justified the operation, for it soon would have developed into a large cyst. The rapid recovery of the patient seemed further to have warranted the early operation, although a sufficient length of time had not yet elapsed to enable one to say that the recovery would remain permanent. With reference to diagnosis in these cases, when the abdominal walls were thin we were sometimes able to determine the nature of the tumor with a good deal of certainty, but in other cases it was not possible to do so. Within the past year two of his friends in this city had opened the abdomen, to find, instead of disease of the tubes or ovaries, uterine fibroids. In each instance the wound was closed and the patient, happily, recovered.

The PRESIDENT inferred that Dr. Lee did not consider that in cases of this kind we were justified in opening the abdomen merely for purposes of diagnosis.

Dr. LEE thought that if the case was a severe and a grave one, destroying the health of the patient, and there was no other way to account for the apparent ovarian disease, the operation was justifiable. He believed, however, that we were in danger of going to extremes, and the two cases which had occurred in the practice of his friends had taught him, in cases of small pelvic tumors, the exact nature of which could not be determined, not to operate unless he felt quite sure that the tumor was the cause of the patient's illness.

The PRESIDENT, in this connection, mentioned a case, and asked the members if they could offer an explanation. A woman came to him, having had a tumor in the pelvis for years, which he found to be easily recognizable, and which by its presence had caused partial prolapsus of the uterus, with all the accompanying disagreeable symptoms of that condition. The

patient assumed the knee-chest position night and morning, and was kept at rest for two weeks, and at the end of this time the mass was found to be diminished to two thirds its original size. The diminution in size took place without any discharge.

Dr. LEE inquired of Dr. Polk whether he felt sure that the mass was a tumor in the sense of being a neoplasm, or whether it might not have been a mass of firmly impacted lymph exudation, which was known often to assume the form of a tumor, and under certain conditions to undergo rapid absorption.

The PRESIDENT said that such an explanation had offered itself to his mind, but he found the original mass very movable, so that when the patient assumed the knee-chest position the tumor repeatedly rose above the pelvic brim, which, of course, it would not have done had it resulted from pelvic cellulitis.

Dr. H. F. WALKER inquired whether the tumor was solid or fluid.

The PRESIDENT replied that it was distinctly fluctuating.

Dr. WALKER said that uterine fibroids sometimes became engorged and gave a sense of fluctuation, while perhaps a week or two later they would be found shrunken and much reduced in size.

The PRESIDENT remarked that in such cases the tumor existed reasonably near the uterus, whereas in the one mentioned by him this distance was markedly increased in the knee-chest position. It had occurred to him that the case might have been one of hydro-salpinx which discharged a part of its contents into the uterus, but the patient gave no history of any unusual discharge.

Dr. LEE said the second case reported by Dr. Dawson reminded him of a pamphlet in which Dr. Robert Battey, of Rome, Ga., described two cases of supposed insanity, due to ovarian irritation, which were cured by oöphorectomy, and he emphasized the fact that several months passed by before the patients showed decided improvement. He ascribed this to the fact that, when the nervous system had been so long affected as to develop decided symptoms of insanity, it required some time to regain its normal state. Probably some of the members of the society had had a similar experience, and had also seen cases bordering on insanity in which the symptoms finally disappeared without operative interference.

Dr. W. M. CHAMBERLAIN said that a lady of this city had been under his care a long time to whom he proposed oöphorectomy, and she afterward consulted other gentlemen who also regarded the operation as necessary and inevitable. The patient became suicidal and homicidal, and it was necessary to remove her to an asylum. The operation, however, was not done. She remained in the hospital six months, and was then returned to her family, not cured, but she had since become perfectly well and returned to her former position in society. Dr. Chamberlain was unable in this case to make a positive diagnosis of pyo-salpinx, but he did not think he had ever seen a woman suffer more intense and protracted ovarian neuralgia than she did, or a neuralgia less amenable to treatment.

The PRESIDENT said this question had been before the Society on several occasions. Dr. Gillette had reported a case bearing on the subject. He did not think the question could be considered in any way settled. There were many cases of melancholia in which there was also undoubted uterine disease, and yet the patients got well of the mental trouble without the uterine or ovarian disease being cured. Interference with menstruation was one of the commonest incidents in mental disturbance, and it might appear to have special connection with ovarian trouble, when in reality that need not be the case. He now had a patient with prolapse of the ovary and retroversion of the uterus who three years ago shot herself through the lower border of the pericardium, the ball passing through the

left lung and lodging near the spine. She recovered from the severe pleurisy, pneumonia, and pericarditis which followed, and was to-day as beautiful a woman as he knew, and in perfect mental condition; yet the uterine and ovarian displacements remained.

INTRA-UTERINE INJECTIONS IN PUERPERAL SEPTICÆMIA.—Dr. L. A. RODENSTEIN then read a paper on this subject. [See p. 688.]

Dr. CHAMBERLAIN said he was glad to hear one of the concluding sentences of Dr. Rodenstein's paper, to the effect that the septic uterus was a relaxed uterus, and presented a wide, or at least a very distensible, os. Such had been his observation, and he had drawn the same conclusion which the author had drawn in a case seen in consultation the present week. He was called in consultation about the middle of the third day after labor. The patient had had a rise of temperature and a slight chill, but Dr. Chamberlain found the uterus firmly contracted, as hard as a billiard-ball; and, in accordance with previous observation, that the septic uterus was a relaxed uterus, he concluded that it was not a case of septic womb, and the final result had proved that it was not. On that fact was based a point in the construction of the tube which went by his name, and which had been criticised—namely, the large size of the instrument. Believing that the septic uterus was always relaxed, and the os patulous, or at least so in the early stage, he believed that the large-sized tube was the proper instrument, and the first were so made, but those made a little later were only three eighths of an inch in diameter. He, however, had never had any trouble in introducing the large tube, and had found that plenty of room remained at the sides to allow of the free escape of the fluid.

Dr. GARRIGUES believed that we had come to a point where all of these cases of puerperal septicæmia could with a great degree of certainty be avoided. Since he had introduced the treatment by bichloride of mercury, described in a paper read before the County Medical Society, December 21, 1883, he had had one hundred and forty confinements in the wards at the Maternity Hospital, which certainly had been considered one of the worst localities for confinement to take place in, one out of every four patients having been seriously ill during his previous term of service and many having died; yet, out of the one hundred and forty cases treated there since the introduction of the method mentioned, there had not been a single case of serious illness. There was one point to which he would call particular attention, as it had been mentioned in the paper; that was with reference to leaving anything within the uterus after delivery. Excellent authorities, for instance, Crédé, taught that it was not necessary to remove pieces of membrane. Dr. Garrigues, however, could not share such a view, because his personal experience was opposed to it. He had seen both very dangerous hæmorrhage and puerperal fever arise from leaving a part of the membranes. He believed that, with the perfected antiseptic measures which we now possessed, the danger of introducing the fingers, or even the whole hand, into the uterus was much smaller than the one to which we exposed the woman by leaving a part of the placenta, or only a piece of the membranes, in the uterus. He would add that he agreed fully with Dr. Rodenstein as to the value of intra-uterine injections when the disease was once there, but he thought we had a drug which ought to be preferred to carbolic acid. He had used carbolic acid for ten years, but had now given it up and substituted bichloride of mercury, and he believed that there was no comparison as to the relative value of the two drugs. This had been proved experimentally and by clinical observation. The enormous difference in the results obtained at such places as the Maternity Hospital, first under the use of carbolic acid, and at present

under the use of bichloride of mercury, proved the great superiority of the latter antiseptic.

HENRY J. GARRIGUES, M. D.,
BENJAMIN F. DAWSON, M. D.,
FRANK P. FOSTER, M. D., *ex officio*,
Committee on Publication.

OBSTETRICAL SOCIETY OF PHILADELPHIA.

Special Meeting, June 6, 1884.

The Vice-President, Dr. B. F. BAER, in the chair.

PYO-SALPINX AND HYDRO-SALPINX.—Dr. WILLIAM GOODELL exhibited specimens illustrating these conditions. In the case of *pyo-salpinx* the lady was unmarried and had suffered from pelvic pains and menorrhagia for several years. Last autumn a tumor was discovered by her physician, who deemed it a fibroid of the womb. Early this year her sufferings became so great that she took to her bed. Very large doses of morphia were needed, and septic symptoms now set in. After she had been in bed for several weeks Dr. Goodell was called to see her. The tenderness of the abdomen was now so great that the examination was made under ether. Even then the diagnosis was obscure, because she flinched and her recti muscles became tense whenever the abdominal wall was pressed upon. A cyst was discovered, but what its nature was it was impossible to determine. Dr. Goodell operated on her at his private hospital. The womb was studded with small fibroid nodules. Posteriorly it had an outgrowth as large as a small egg. Closely adherent to the womb, to the pelvic fascia, and to the intestines was a thick-walled cyst of the left ovary as large as the largest orange. The corresponding oviduct was very thick and enlarged to the size of a small sausage. It and the cyst were filled with a very dark purulent fluid, although there was no communication between them. The lower end of the cyst had become necrosed and was so thinned that it would very soon have given way at that point. On account of the presence of fibroids in the womb the right ovary also was removed. Attached to the fimbriae of the oviduct were three very beautiful pedunculated vesicles, while two others not yet pedunculated lay in the stroma of the broad ligament. The recovery of the lady was uninterrupted.

In the case of *hydro-salpinx*, the patient was a widow, aged thirty-seven, who had been sent to him in order to have her ovaries removed. Severe pains began a week before the menstrual flux, culminating during the flow and continuing one week longer, then fading gradually away. For three weeks out of every month she was confined more or less to the recumbent posture, and wholly so during the menstrual week. A tear of the cervix and one of the perinæum had been well repaired by two surgeons, but with no improvement. Dr. Goodell wished her at first to try the rest treatment, with massage, electricity, and graded muscular movements, for he had repeatedly cured cases of this kind by such a mode of treatment. She was, however, too poor to take this treatment privately and therefore was urgent to have her ovaries removed. The operation was performed fifteen days before the meeting, and she was now doing very well indeed. The ovaries as exhibited were much enlarged and showed marked follicular degeneration. From this condition, Dr. Goodell thought that nothing short of the operation would have cured her. Attached to one oviduct was a delicate vesicle with a thread-like stem of over an inch in length. In view of the frequency with which they were found, he could not but think that these vesicles played some rôle in the economy, and that they had sometimes a pathological bearing. He had on several occasions met with small post-uterine cysts which burst either spontaneously or under the pressure of an ordinary vaginal examination. Taking advantage of this fact, he had

quite recently burst one designed by bimanual pressure. Such delicate cysts, and also those very movable ones which remained small, he was disposed to attribute to these vesicles. After bursting, these cysts sometimes filled again. One he had known to do so at least six times before it disappeared. Small ovarian cysts had, in his experience, thick walls, and, further, they rarely remained small any length of time. Dermoid cysts, on the other hand, often remained stationary for years, but they were generally not very movable, and they also had thick walls.

Dr. ALBERT H. SMITH had found these cases of pyo-salpinx very difficult of diagnosis. He had been present at an operation by Mr. Knowsley Thornton, of London, in a case in which the lesion was double, and both tubes and ovaries were removed. Rupture had occurred previously, and had been followed by peritonitis. The patient recovered.

Dr. B. F. BAER inquired if Dr. Goodell would recommend rupture of cysts arising from the hydatids of Morgagni.

Dr. GOODELL would consider it good surgery, for the purpose of preventing the further growth of the cyst. He had always found the fluid in small cysts to be unirritating.

Dr. SMITH remarked that Schröder held that the fluid of an ovarian cyst was not noxious to the peritonæum. He made no effort to protect the peritoneal cavity from its ingress during an operation, and yet his statistics showed a remarkable success.

In response to a question by Dr. C. Meigs Wilson, Dr. GOODELL stated that the dressing of the wound after the operation was glycerole of carbolic acid, with the Lister gauze.

HYSTERECTOMY.—Dr. GOODELL also gave the following history of a case:

The woman was unmarried, aged forty-seven. Her menstruation began to be free in 1867. A year ago it became so exhausting that she could not pursue her trade as a seamstress. On April 30th she consulted Dr. Goodell, who found the whole abdomen filled with multiple fibroids of the womb. The cervix had disappeared, and the os uteri lay so high up that it was not possible to introduce the sound. The operation was performed at the hospital of the University of Pennsylvania on May 22d. One outgrowth as large as the two fists contained a cavity filled with cheesy matter, and was so adherent to the abdominal wall and intestines as to need the knife for its release. It was possibly the right ovary, but he was by no means certain. Kæberle's wire clamp was passed around what corresponded to the neck of the womb, but it was as large as his arm above the elbow. The woman's recovery thus far had been uninterrupted. The temperature reached 100° F. but once. The clamp fell off on the sixteenth day, leaving a very deep funnel-shaped pit. He had intended to exhibit the specimen, but it was too bulky to carry, and also had become quite offensive. In this case, had he been able to reach the ovaries, or to discover them, he would have removed them in preference to performing hysterectomy; but the firm adhesions prevented the rotation or the lifting up of the tumor; hence the ovaries were inaccessible. Sometimes, even when a uterine fibroid could be lifted out of the wound, and the ovaries reached, these organs were so imbedded in the fibroid, or so drawn out in ribbon form on the surface of the tumor, as to make their complete removal impossible. When, however, the ovaries could be removed with safety, the operation was a most promising one, as he could attest from several most successful cases.

PARTIAL PLACENTA PRÆVIA.—Dr. W. T. TAYLOR reported the case of an Englishwoman, aged forty-six years, the mother of ten children, who came to see him in December, 1883, in consequence of abdominal pains, headache, and vertigo, with a suppression of her menses which she attributed to the "change of life," as she had been irregular for a year before. She also had

numbness with tingling in the hands and feet, and had not been so affected in any former pregnancy. Consequently she would not believe herself to be in that condition until some weeks later, when she quickened. In the month of February last she had enlargement of the veins of the legs, with œdema of the feet and ankles, for which she took occasional doses of potassium bromide, with a solution of cream of tartar (one ounce to water one pint) to be taken freely. By this treatment she was temporarily relieved. On March 27th she had abdominal pains and a profuse hæmorrhage, which saturated her clothing and greatly alarmed her. On examination, Dr. Taylor found the os uteri high up and slightly open. Although the hæmorrhage diminished, yet the pains recurred at intervals, and he fully expected labor would soon begin. Under the use of equal parts of wine of ergot and solution of sulphate of morphine, she began to get easier, and in a few days was out of bed and able to resume her household duties; feeling more comfortable as the enlarged veins were smaller, her feet and ankles had diminished in size, and the headache was gone entirely. He told her that nature had come to her relief and bled her without his ordering it. Feeling satisfied that this was a case of placenta prævia, and that there was no immediate danger, he concluded that the most prudent course was to let nature alone and wait until labor began. She had no more trouble until May 10th, when she passed a large clot of blood and complained of slight pains in the abdomen. These occurred occasionally for two days, when the membranes ruptured and a sudden gush of water, followed by a flow of blood, indicated that labor had begun. On examination, he discovered within the os a spongy, ragged, bleeding mass of tissue, which was recognized as the placenta; with each pain the flow of blood increased as the cervix dilated. Sweeping his index-finger around within the mouth of the womb, as far as he could reach, to detach the placenta from the uterine walls and assist the first stage of labor, he felt the fetal head beyond. To arrest the bleeding, which, if it continued, would exhaust the mother and destroy the child, he plugged the vagina completely with strips of old muslin well saturated with lard, and waited patiently for the os to dilate and the head to advance, giving at the same time occasional doses of quinine and wine of ergot as a tonic and stimulant. In about an hour the advancing head had expelled a part of the tampon, and, on removing the remainder, it was found that the bleeding had ceased and that the vertex was presenting in the left occipito-posterior position. Auscultation revealed a feeble fetal circulation, but, as the pelvis was roomy and the patient somewhat exhausted, he gave her freely of milk punch until her pulse became stronger, which it did in half an hour, when, as the head had ceased to advance, he applied the forceps and delivered her of a medium-sized girl, which in a few minutes began to cry with some vigor, contrary to his expectations. The child's vitality had been preserved by the adhering part of the placenta, which then came away quite easily. A teaspoonful of fluid extract of ergot contracted the womb firmly. The patient was weak for several days, but, under the use of tonics with nourishing food, she soon recovered her usual strength.

Dr. SMITH remarked that this case, being partial and without profuse hæmorrhage, could have been best carried through by rupturing the membranes and bringing down the head, which would have stopped the hæmorrhage so soon as it engaged in the superior strait. Under what circumstances, he asked, were we warranted in interfering? If the hæmorrhage was alarming and the patient exhausted, she was in a poor condition to bear interference, and, on the other hand, we had no right to interfere if there was no pain or hæmorrhage. To interfere by manipulation was very dangerous, unless the uterine contractions were rapid and effective, after labor had once begun. The

position of the child should be carefully and accurately determined by external manipulation before interference became necessary, so that we might know where to seek the feet, if turning became imperative. When the placenta prævia is complete, dilatation of the os caused a terrific hæmorrhage, the blood streamed from the patient like water from a hydrant or a small fire-plug, and death came very quickly. Only perfect knowledge of the condition of things and the position of the child would enable the physician to avert the doom. Now, as to the tampon, he would not use it. It hid the hæmorrhage, which might be going on profusely behind it, as had been so vividly described by Dr. Goodell, in his paper on "Concealed Accidental Hæmorrhage of the Gravid Uterus," in vol. ii of the "American Journal of Obstetrics," in which he had shown that the woman might bleed to death without one drop of blood escaping externally. The tampon concealed the hæmorrhage without necessarily preventing it, and while it remained in place one hand of the physician should be constantly on the patient's pulse, to notice instantly any failure of the heart, while the other should be on her abdomen, to note any changes in the size of the uterus or the position of the fœtus. In Dr. Taylor's case the treatment was beyond criticism, because the result had been happy.

Dr. GOODELL agreed with Dr. Smith that placenta prævia was the most formidable complication in obstetrics. No general rule could be made applicable to the treatment of all cases. In partial ones the membranes should be ruptured and the head brought down. It must always be borne in mind that in these cases the implantation of the placenta caused increased vascularity and thickness of the cervical walls, that they were easily ruptured, and that, if torn, they bled profusely. There was greater danger of septicæmia from absorption of decomposing lochial discharges when passing over this surface if it was torn. He well remembered one case in which he attended years ago in consultation with the late Dr. Augustin Fish, in which, in consequence of what he now considered undue haste, lacerations of the cervix occurred, and, although the labor terminated happily, septicæmia set in a few days later and resulted fatally. It would have been better in that case to tampon. When the placenta was not central, there was very little danger, but there was some. The tampon might be used, but the pulse must be constantly watched and frequent abdominal palpation should be made. He had been struck with the method practiced by Dr. Ellwood Wilson more than twenty years ago. It consisted in gentle digital dilatation of the os; introducing first one finger, then two, and so on, and, so soon as sufficient space was obtained, giving ergot, and performing podalic version and extraction. Very few practitioners advised that method. Dr. Goodell had not met with many cases, and the one spoken of above was the only fatal one. He had used Barnes's dilators, taxis, strength, and courage, and had tried to adapt his treatment to the indications of each particular case.

Dr. W. H. PARIS thought the tampon was not used so frequently now as it was a few years ago, either in the form of Barnes's dilators or in that of the vaginal plugs. Under similar circumstances he would probably do as Dr. Taylor had done. Partial placenta prævia was not very dangerous, but in complete placenta prævia the hæmorrhage was excessive. In one case he had tamponed for several hours, when, the os being dilated, he etherized the patient and rapidly extracted a living child. The mother was in imminent danger of death from hæmorrhage. The abdominal aorta was compressed, and ice was applied to the cervix, but without success. The hæmorrhage was controlled by the application of a cloth wet with Monsel's solution to the denuded cervical and uterine surfaces.

Dr. TAYLOR had used the tampon in several cases of partial

placenta prævia and in numerous cases of abortion, and had never yet known bleeding to go on behind it. The line of treatment practiced in this case had always proved satisfactory as regarded results.

Dr. GOODELL remarked that the womb at term was large and concealed hæmorrhage might be free enough to cause death, but there was no such danger in an abortion at two or three months.

W. H. H. GITHENS, M. D., *Secretary.*

Reports on the Progress of Medicine.

OPHTHALMOLOGY.

By CHARLES STEDMAN BULL, M. D.,

LECTURER ON OPHTHALMOLOGY AND OTOTOLOGY IN THE BELLEVUE HOSPITAL MEDICAL COLLEGE; SURGEON TO THE NEW YORK EYE AND EAR INFIRMARY; OPHTHALMIC SURGEON TO ST. MARY'S FREE HOSPITAL FOR CHILDREN AND TO THE NURSERY AND CHILD'S HOSPITAL.

THE THERAPEUTIC VALUE OF IODOFORM IN DISEASES OF THE EYE.—Alker ("Arch. f. Ophthal.," xxix, 4) formulates the results of his observations upon this subject: 1. Iodoform is well borne by the majority of patients, in whatever form it may be employed. 2. It is of very marked value in all ulcerative processes in the cornea, especially in those forms of hypopyonkeratitis dependent upon a basis of infection, although there are some isolated cases in which iodoform as well as the transverse splitting of the cornea fails to hinder the total suppuration of the cornea. 3. It acts not only as an antiseptic but also as an aseptic in all recent cases of injury, whether they are accidental or operative. 4. It possesses a positive power of clearing up the opacities of scrofulous pannus and deeper lying infiltrations.

CONTRIBUTIONS TO THE ANATOMY OF THE OPTIC NERVE.—Vossius's article (*Ibid.*) is somewhat lengthy, as are also his conclusions, an epitome of which is here given: 1. The point of entrance of the central vessels into the optic nerve lies from 10 to 12 mm. back of the eyeball, at its lower periphery, in the lower and outer quadrant. This constant relation of the point of entrance of the central vessels should cause no surprise, when we consider the manifold variations of the vascular apparatus, and that in the embryo the fetal ocular fissure is always situated below. 2. In certain animals the central vessels are likewise sunken to the lower periphery of the nerve. 3. A change of position of the point of entrance from its location in the embryo has taken place, by which the fetal ocular fissure comes to lie downward and inward. The rotation of the optic nerves corresponds to an angle of at least 90°. 4. This change of position of the vessels is a powerful support for the old view recently advocated by Manz, that the macula is the remains of the fetal ocular fissure, and does away with the difficulty which exists in the lateral position of the macula. 5. The eyeball also rotates, the rotation being particularly noticeable in the rectus superior, which in the embryo is lateral, but in adults is more under the middle of the orbital roof. The cause of the torsion is the lateral displacement of the ocular vesicle forward in the parallel position of the ocular axes, and the disproportion between the increase in length of the optic nerve and the part that it plays in the length of the orbital axis. By a rotation backward of the optic nerve, the macula and point of entrance of the vessels are again found in their fetal position, downward and inward. 6. While in man the insertion of the optic nerve at the posterior pole of the eye occurs in the lower and inner quadrant, and the long posterior ciliary arteries run nearly accurately in the horizontal meridian, in certain of the mammalia

the optic nerve is inserted outside of the vertical line, while in the cat it is inside. 7. In its intracranial course the nerve receives its arterial supply mainly from the arteria corporis callosi. In the optic foramen, a peculiar vascular and interstitial connective-tissue structure is developed. The arterial vessels arise from the ophthalmic or its muscular branches; its branches lie on the under surface of the nerve. The venous blood passes through the vena centralis posterior into the cavernous sinus, and debouches from the nerve close to the entrance of the latter into the optic foramen. 8. The central retinal artery assists in the nourishment of the posterior orbital part of the optic nerve by means of a moderately large branch which runs backward, and is accompanied by a vein which empties into the central retinal vein. 9. The circulatory and nutritive relations of the optic nerve in the optic foramen, the number of trabecular divisions, the proximity of the nerve-trunks and their union through the medium of the loose meningeal cellular tissue, all favor the occurrence of an inflammation at this spot, a retrobulbar neuritis, which develops in both nerve-trunks at the same time, or in one soon after the other, and which may pass from one nerve to the other without involving the chiasm. The inflammatory process is most pronounced in the central region of the cross section in which the macula fibers lie, and hence the nerve-bundles in this region are more hindered in their function than the peripheral fibers. This is explained by the fact that the trunks of the entering vessels are found at the periphery of the optic nerves, while their capillary terminations are found in the center.

ON THE OPHTHALMIA PRODUCED BY JEQUIRITY.—Von Hippel's article is a fair judicial criticism of the views promulgated by von Wecker and others as to the value of jequirity in the treatment of obstinate granulations and pannus (*Ibid.*). He disagrees with Sattler's view that the jequirity-ophthalmia is an infection disease. He thinks that the characteristic conjunctivitis may always be produced by the application of the infusion, but that the intensity of the inflammation is less after instillation than after the direct painting of the everted conjunctiva with the infusion. A dosing of the inflammation, by frequent or infrequent application, by the use of stronger or weaker concentration of the infusion, is only possible within wide limits. As a rule, the ophthalmia is the more intense the longer and more frequently the agent acts upon the conjunctiva. The artificially produced jequirity-ophthalmia can not be regarded as absolutely safe for the patient, while the pain of the application does not specially commend it as a therapeutic agent. In fresh trachoma the old treatment by iced applications and silver nitrate or cupric sulphate is much more successful and less dangerous and annoying to the patient than the treatment by jequirity. In the inveterate forms of pannus, in which the conjunctiva is pale and extensively covered by hard, yellow granulations above the level of the mucous membrane, the case is very different. Here the jequirity treatment gives good results, for the great hyperæmia and serous infiltration of the lid which accompany the action of the drug exert a beneficial influence upon the retrograde metamorphosis of the granulations, causing them in some cases to entirely disappear, without producing much shrinking of the conjunctiva or distortion of the lids. Pannus is also acted upon favorably by the jequirity infusion, and thus the vision is very often materially improved. Hippel has, however, never been able to bring about favorable results in so short a time as Wecker states, and in most of his cases from three to four months elapsed before the granulations disappeared. Good results are also gained by jequirity in cases of trachoma ending in consecutive atrophy and shrinking of the conjunctiva and dense, opaque pannus of the cornea. Von Hippel does not admit Sattler's view of an infection disease because of the ab-

sence of a stage of incubation. Moreover, if the jequirity-ophthalmia were an infection disease, the secretion or small bits of the croupous membrane, on being transplanted to a healthy eye, would here cause the same inflammation, but this von Hippel has never succeeded in producing. So long as no one has succeeded in demonstrating definite peculiarities of form and development which distinguish the jequirity bacillus from all other bacilli, it can not with justice be regarded as specific. Hippel does not regard Sattler's experiments in the cultivation of the jequirity bacillus as entirely successful, for in the conjunctival inflammation produced by it "the enormous swelling and board-like hardness of the lids" were conspicuous by their absence. He explains the peculiar action of the jequirity-bean in producing a severe conjunctivitis as due to the presence in the bean of a chemically different substance or an undeveloped ferment, which by contact with the conjunctiva excites in it a violent inflammation.

THE EXPERIMENTAL PRODUCTION OF SYMPATHETIC OPHTHALMIA.—Deutschmann (*Ibid.*) here contributes a second article upon this subject, of which the following is a résumé: A sympathetic ophthalmia has experimentally been successfully produced in the rabbit—that is, after infection of one eye of an animal, the other eye became spontaneously affected after the lapse of a certain time. The affection of the second eye began with an inflammation of the intraocular end of the optic nerve, as was proved by the ophthalmoscope; thence it spread to the retina and vitreous, and finally to the uveal tract. Hence the optic nerve and its sheaths must be recognized as the channel of extension for the sympathetic affection, but it is not possible to decide whether the nerve or the sheaths are the more involved. The inflammatory symptoms in the channels of extension are but transient; only in the beginning do they have any degree of intensity, and they soon diminish when they have effected their purpose in infecting the second eye. It is probable that a later stage might be recognized in which the channels of communication would be found entirely free of all signs of inflammation. But the propagated inflammatory process spreads where it finds a suitable surface in the second eye, and also on the surface of the pia mater at the base of the brain.

INFLAMMATION OF THE CAPSULE OF TENON.—Bergey (*Ibid.*) has had the opportunity of examining a phthisical eyeball which had been lost from inflammation of the capsule of Tenon. The inner lamina of Tenon's capsule was thickened, its fibers were loosened, and in places infiltrated with round cells. Upon the surface of the capsule there was a layer of connective tissue, consisting of undulatory fibers with numerous longitudinal and fusiform nuclei, and some round cells. This newly formed connective tissue was traversed by newly developed blood-vessels, which communicated with the blood-vessels of the sclerotic and inner lamina of Tenon's capsule. Between the fibers of connective tissue were masses of endothelial cells with two nuclei and nucleoli. The tendons of the ocular muscles were surrounded on both outer and inner surfaces by this newly formed connective tissue, but no change was noticed in the tissue proper of the tendons. Careful examination showed that this newly formed connective tissue extended backward nearly to the optic nerve, and was prolonged into the supra-vaginal space which connects with Tenon's lymphatic space. The result of the inflammatory process is complete obliteration of Tenon's space by this exudation, which must exert considerable compression upon the vasa vorticosa.

CLINICAL KERATOSCOPY.—Wecker and Masselon ("Annales d'oculistique," Nov.-Dec., 1883) present a modification of a previous instrument of Wecker for determining errors of refraction, especially astigmatism. In the modified instrument the two opposite sides of the square may be caused to approach

each other, right and left, by means of a screw, and it is possible in a case of regular astigmatism to transform the square into a rectangle in such a way that it is reflected upon the astigmatic cornea according to a square. This transformation is accomplished after a certain number of turns of the screw, which also cause a runner to move simultaneously along a graduated scale, which indicates in dioptries, or fractions of a dioptric, the displacement of the sides of the instrument, which it has been found necessary to produce, in order to give a perfectly square reflection upon the astigmatic cornea. By employing this instrument, the inventors profess to have done away with the necessity of a registering astigmometer or keratoscope, and at the same time are enabled to demonstrate plainly to students the deformity of the reflection produced by corneal astigmatism. They have also found that corneal opacities, uncomplicated with facets, almost always give rise to a sensibly regular and correctable astigmatism.

ASTIGMATIC KERATITIS.—Martin (*Ibid.*) contributes a second article on this subject. Many cases of severe and repeated keratitis are complicated by a high degree of astigmatism, and they occur so often as to force upon us the conviction of the existence of a union of cause and effect between the asymmetry of the cornea and the appearance of so-called scrofulous keratitis. The degrees of astigmatism which are met with in cases where blepharitis exists alone are always small, and hence, probably, they have not been deemed capable of causing inflammation of the lids. The unequal contractions of the ciliary muscle, provoked by the astigmatic state of the cornea, have only been recognized for a comparatively short time. Another difficulty in the way of positively admitting the diagnosis of astigmatic blepharitis was found in the comparative rarity of inflammation of the ciliary margin of the lids in persons who were known to be astigmatic; and this same difficulty has existed in the matter of astigmatic keratitis. Of course, not all the persons who have what is commonly called scrofulous keratitis are not astigmatic; nor are all patients with keratitis and astigmatism scrofulous.

THE DOWNWARD OR INFERIOR CONUS.—Szili ("Centralblatt f. prakt. Augenheilk.," Dec., 1883) has been investigating the conus which is found at the inferior margin of the optic disc in some astigmatic eyes, with special reference to the form and degree of astigmatism. He thinks that in the majority of the cases the astigmatism is due to the conus in this direction. A considerable portion of the lower half of the posterior wall of the eye is distended with the conus, and bulged out backward to a corresponding degree. The entire profile of the optic nerve seems more or less so rotated on its axis that its upper part has the appearance which resembles the so-called inner half of the disc in normal eyes, while correspondingly the external half of the papilla seems to have become the lower. The direction of the conus, more or less downward, sometimes downward and inward, and the physiological excavation, when the one or the other or both are present, correspond exactly to this rotation, and so does the arrangement of the central vessels. As far as the trunks of these vessels are visible, they show usually a somewhat oblique direction from above and outward, downward and inward; the branches running upward divide at a much more acute angle than those running downward, and in their further course seem to fit themselves to a shorter cut than the inferior vessels.

UNILOCULAR CATARACT WITH AN ANOMALOUS CONDITION OF THE BONES OF THE SAME SIDE.—Heuse (*Ibid.*) reports a third case of this kind. The cataract was in the right eye, and was of the posterior polar character, with four short lateral processes, and at the center it extended toward the center of the lens like a short cone. In the anterior laminae of the lens there

was a striated opacity, which had no visible connection with the polar cataract. The left eye was normal. The patient was a boy, four years old, with divergent squint. On the right side of the forehead there was a large projection or swelling, which, on examination, proved to be a rachitic bulging of the bone, had appeared during the first year of the child's life, and at the same time there was a marked rachitic development of the right side of the chest.

A NEW METHOD OF DETERMINING THE REFRACTION OF THE EYE IN THE UPRIGHT IMAGE.—Burchardt (*Ibid.*) recommends a method of determining the refraction, which he considers valuable in many cases, especially as a method of control. He employs, instead of a candle-flame, opaque black letters printed upon a translucent plate of glass. The spaces between the letters are illuminated by a light made up of rays approximately parallel, and the sharp image of the letters thrown upon the retina of the eye was used to determine the refraction from the position of the glass plate. In making the examination, to the exact understanding of which a drawing is necessary, he employs a bright light placed in the focus of a lens; a translucent glass plate with the black letters running on a horizontal bar which is graduated in centimetres; a second convex lens of 10 cm. focus, and a perforated plane mirror. By means of a band of 10 cm. in length, which starts from the upright support of the second convex lens, and passes round the handle of the mirror to the cheek of the patient, the latter's eye may readily be placed in such a position that its distance from the mirror, plus the distance of the lens from the mirror, is equal to 10 cm. The graduated bar is fastened on a movable standard, so that the source of light, the centers of both lenses, the movable letters, and the hole in the mirror are all in the same line.

THE ASSOCIATION OF SENSATIONS OF TASTE AND SMELL WITH COLORS, AND THE ASSOCIATION OF SOUNDS WITH SENSATIONS OF FORM.—Hilbert ("Klin. Monatsbl. f. Augenheilk.," Jan., 1884) reports another case of this singular anomaly in the person of a young woman, aged twenty-four, who came of a healthy family and had never had any disease of the nervous system. The double sensations had been experienced in early childhood. A sensation of color was not excited by every sensation of smell or taste, but only by unpleasant odors or tastes, probably because the latter caused a stronger irritation. The taste of one unpleasant kind of beer excited the sensation of brown, while another excited the sensation of gray. In the same way an ugly brown was produced by the taste of burned sauce used in roasting. The characteristic odor of young dogs likewise produced the sensation of brown. The odor of old cheese was associated with the sensation of brownish-green, while the taste of the same cheese produced a sensation of yellow. Slight sensations of taste and smell excited bright colors, while intense sensations of the same sort produced deeper colors. The playing of certain melodies produced sensations of forms, especially of persons, and the latter were associated with sensations of certain sounds.

DOES MECHANICAL IRRITATION OF THE TRUNK OF THE OPTIC NERVE PRODUCE A SUBJECTIVE LIGHT-SENSATION?—Landesberg (*Ibid.*) has made in every suitable case during the last three years a careful investigation in regard to the reaction of the stump of the optic nerve to mechanical irritation. The cases in which enucleation had been performed, and which were subjected to examination, were seventeen in number, and the method was as follows: 1. The patients were left entirely in the dark in regard to the object of the investigation. The stump of the optic nerve was pressed upon by a small probe or squeezed with the blades of the forceps, so as not to attract any attention, and the patient was then asked what was experienced during the manipulation. Sixteen persons complained of pain. Only one patient stated that, at the moment of pressure, he

perceived a lightning-like flash in the field of the enucleated eye. 2. The patients were then instructed as to the significance of the experiments, and were urged to observe carefully whether they perceived any subjective light-sensation at the moment of the mechanical irritation of the stump of the optic nerve. Three patients then asserted that on pressure they perceived a sensation of light on the side of the enucleated eye, which they described as lightning with colored, zigzag margins. In thirteen cases all light-sensations were denied. This negative result might depend upon two causes. Either the mechanical irritation of the stump of the optic nerve in these cases really produced no subjective sensation of light, or the mechanical irritation *did* produce such a subjective light-sensation, which was not consciously recognized or mentally seen, from lack of either attention or intelligence on the part of the patient. If it were possible to present to the patient an object of comparison, or visibly demonstrate what was the object of experiment, the result might be somewhat modified. In order to settle this question, Landesberg brought each patient into a darkened room and produced phosphenes by pressure upon the sound eye, and instructed them that he wished to determine whether pressure on the stump of the optic nerve of the enucleated eye also produced light-sensations. At the next trial, four patients stated that they saw flashes of light at the moment of irritation. In nine cases out of the seventeen the result was invariably negative.

THE PATHOLOGICAL ANATOMY OF RETINAL HÆMORRHAGES.—Thalberg ("Archiv. für Augeneheilkunde," xii, 2 and 3) gives the result of the microscopical examination of a retinal hæmorrhagic effusion in the body of a patient who had died of progressive pernicious anæmia. The nerve-fibers beyond the bend at the margin of the disc were thickened and loosened. The blood-vessels, especially the veins and capillaries, were greatly distended, so that in many cases an enlarged vein pushed all the retinal layers forward toward the choroid, or else had so pushed them aside as to tear them, the laceration being filled by a finely granular mass with some red and white blood-globules. Every blood-vessel was surrounded by a mass of blood-corpuscles, and, even where there were no blood-vessels, isolated blood-corpuscles were found in the nerve-fiber layer, the ganglion-cell layer, and the inner granular layer. No rupture in the wall of a blood-vessel could be found, nor any connection between the blood-corpuscles massed in the adventitia and those within the vessels. In cross-sections of the arteries, the lymph-space was only visible in places.

THE ÆTIOLGY AND THERAPEUTICS OF RETRO-BULBAR INFLAMMATION OF THE ORBITAL CONNECTIVE TISSUE.—Pagenstecher (*Ibid.*) reports a case of this nature occurring in a boy, aged nine, which he thinks was due to a spread of the infection from an inflamed maxillary sinus. The case is of interest, though too long to report in full. There was but little reliance to be placed on the statements of the patient, and there was no proof of any inflammation of the periosteum at the root of the extracted molar; but there was little doubt of a direct connection between the disease of the tooth and the inflammation in the orbit. The extraction of the tooth certainly produced a marked improvement in the orbital inflammation. Inflammation of the orbital cellular tissue by direct infection from a diseased tooth, through the medium of the lymph-channels, though of rare occurrence, is so certain a pathological fact that, in every case of cellular inflammation of the orbit, a careful examination should be made of the buccal cavity, alveolar arches, and maxillary sinus; and, where diseased molar teeth exist, they should be extracted, if the caries or abscess can not be reached in any other way.

AN OCULAR LESION AFTER A STROKE OF LIGHTNING.—Pagenstecher (*Ibid.*) reports the history of a child, aged ten, who was

struck by lightning, and remained unconscious for a number of hours. Then an attack of vomiting set in, and consciousness slowly returned. Very soon the eyelids became swollen, and, several days later, when seen by a physician, the levator palpebræ was paralyzed, though the vision was apparently intact. About a year later, however, there was noticed a distinct loss of vision. When Pagenstecher saw the case, vision was as follows: R. E. Jäger 24; L. E. Jäger 19, and $\frac{6}{60}$. Both corneæ were clear. The right pupil was irregular, long oval, and dilated, and reacted slowly to direct light, but rapidly to reflex influence. Atropine produced but little influence, while eserine quickly produced myosis. The left pupil was circular, and reacted promptly to light. In the posterior cortex of both lenses was a large, irregularly quadrangular, sharply defined, dense opacity, somewhat larger in the right eye than in the left. The rest of the lens in each eye was clear. The fundus could not be accurately seen, but the visual field was normal. The right lens was subsequently needled, and, after three months and a secondary capsular operation, a clear pupil was gained, but no improvement of vision resulted. The fundus appeared still veiled; but there was no white atrophy of the optic nerve.

Miscellany.

THE COMPOUNDING OF PRESCRIPTIONS BY PHYSICIANS.—Dr. L. S. Blackwell, of Perth Amboy, N. J., writes to us expressing his conviction that, in view of the frequent occurrence of alarming results, and even death, from the accidental administration of poisonous doses of drugs—a matter on which we lately commented—the adoption of measures to reduce errors on the part of physicians and apothecaries to the minimum deserves serious consideration. Although, he says, of the five cases to which reference was made in our article, the mistake occurred in the physician's prescription in two, and from having a bottle incorrectly labeled in another, it has not been shown that the results would have been the same if the prescription had been compounded by the physician. In its preparation there would have been an association of ideas in the prescriber's mind, in regard to the harmony between the symptoms and the therapeutics of the case, which would have pointed to the existence and rectification of any error in the phrasing of the prescription. He adds that, if the mistake is made by the physician, with the prescription in the hands of the apothecary, "the element of safety" is not apparent to the prescriber.

Dr. Blackwell advocates the practice of physicians preparing their own prescriptions, and he argues—quite correctly, we think—that advantages would result from the time that could be given to reflecting on the case between the visit to the patient and the return home, apart from the consideration that the prescription would then be written under circumstances that would tend to guard against the prescriber's mind being distracted by interruptions. He remarks that his plan would do away with the need of rousing a dispensing clerk at night, with the certainty of considerable loss of time and the risk that naturally results from having a prescription put up by a sleepy and perhaps half-conscious man. For himself, he has followed the plan of preparing his own prescriptions for the past quarter of a century, and states that he can not recall a single instance of error. He does not think that this experience differs materially from that of others who have followed a like course—a course which, he believes, possesses advantages and furnishes greater security both to patients and to physicians.

A DENTIST'S SOLICITUDE.—"LYON medical" tells the following story: A dentist is extracting a molar. "Don't cry out like that," he says to the patient. "You suffer at seeing me suffer," replies the patient. "No, I'm speaking on account of the neighbors." "Does it disturb them?" "If that were all! But it takes away their confidence."

Lectures and Addresses.

THE OPENING ADDRESS

BEFORE THE

AMERICAN CLIMATOLOGICAL ASSOCIATION.*

By FREDERICK I. KNIGHT, M.D., BOSTON,
First Vice-President.

GENTLEMEN OF THE AMERICAN CLIMATOLOGICAL ASSOCIATION: It was with exceeding regret that I learned, a few days ago, that our president would be unable to attend this the first regular meeting of the Association, and that I was asked, in consequence, to preside over your deliberations. From him, who has been so long interested in the study of climatology, we had expected, besides his valuable aid in organization, to receive much counsel in regard to the direction of our future observations and work. I am sure you will all join with me in sending him our regrets, greetings, and hopes for his speedy recovery.

Our professional brethren will probably look to the minutes of our first meeting as to the preface of a book, to see what reason we can give for our existence, for creating ourselves an independent organization. Our answer is that we believe that more can be accomplished by a small body of thoroughly interested men, working independently in a limited field, rather than as a part of a great combination; and, although there is less objection to the grouping of climatology with State medicine and hygiene than in classing together in one section such totally distinct specialties as ophthalmology and laryngology, we feel that the interests of climatology will be better served by its isolation. It so happened that the gentlemen who responded to the call to organize this society were particularly interested in one class of diseases, and expressed their desire at the preliminary meeting that the object of the Association should be the study of climatology and the diseases of the respiratory organs. Climate is, however, just as potent in working changes in other parts of the economy as in the domain of the respiratory organs, and it may be questioned whether it is advisable to extend our study, if we wish it to be most effective, beyond what can be legitimately included under climatology and medical geography.

One of our first objects in attempting to revive and further a knowledge of climatology should be to place before the general profession, for every-day use, well-known and indispensable facts about climate. This should include not only information about localities and the general indications for their selection as places of resort, but also of the ways of travel, and the accommodations for living after arrival at them. For climate is but an adjuvant, and can accomplish comparatively little without proper food and shelter for patients. The houses of the natives in warm climates are built to be cool in summer rather than for warmth in winter, and, moreover, a person leaving a cold climate has often become accustomed to a much warmer house than would

have been essential to his comfort if he had lived in a milder climate. Notice, as bearing on this point, the fact that we heat our houses in the spring long after the temperature has reached the grade at which we had no fires in the autumn. So it happens that houses in the South which will be comfortable for the Northerner are often hard to obtain. Most of the hotels, however, are now well constructed. Something definite also should be known about the food available at the locality chosen, the means of obtaining such material as the patient requires, if he is to keep house for himself, and especially the methods of preparation, if he must depend on hotels and boarding-houses. In most cases also we should be sure of being able to secure good medical supervision of our patients, as essential to their complete welfare.

During the past thirty years the mind of the medical practitioner has been absorbed in the pleasure and satisfaction of exact diagnosis, to the detriment of the art of therapeutics, except when exact diagnosis indicated a pretty certain remedy. But that art of therapeutics which looked for its indications in combinations of symptoms, many of them, perhaps, subjective, and which was often apparently but a palliation of symptoms, has undoubtedly declined. We have inquired earnestly enough what is the matter with our patients, but not carefully or earnestly enough "what can we do to cure or relieve them?"

I admit that this branch of medicine is often dull and unsatisfactory, but it is that for which we are taking the community's money, and they are entitled to the best possible return. In this decline of the study of therapeutics the knowledge of climate has suffered, and the extent of the advice which most practitioners offer to-day is, "Try a change," or "Go South." We sometimes even hear it asked if change of climate can make much difference, after all, in the patient's condition. One of my instructors in therapeutics used to say, "If you don't believe that drugs accomplish anything in the human system, take an overdose of some of them." I should point the doubter about the effects of climate to the changes in the types of man produced by residence in different quarters of the globe, and especially to the cumulation of effect seen in succeeding generations, and notably in the change in the families of immigrants to this country, so great and rapid that in one or two generations we often fail to detect their ancestry. In extending our knowledge of this subject, our own members will occupy a vast field with almost every variety of climate, which has been as yet but little explored. It is unnecessary to point out to gentlemen here the factors of climate which require investigation, elevation, temperature, moisture, ozone, forests, soil, winds, sunlight, the vicinity of large bodies of water, etc. We must study the effect of these factors not only on the disease which may seem to indicate the change of climate, but upon the healthy organs of the patient also; and, if a permanent change is to be made, the probable effect of it upon other members of the family, especially the children, for it is often the children who derive the greatest benefit from a well-advised change of abode. Something can be done by our members, I hope, especially by those

* Read at the first annual meeting, held in Washington, May 3 and 5, 1884.

who reside at health resorts, to increase the comfort of invalids at these stations. Advice as to the construction of hotels and the food-supply should be freely given, even if it has to be volunteered. I think that in many localities the cottage plan might be adopted with benefit—i. e., instead of patients with all diseases and in all stages being crowded together under one roof, they should be put into small cottages about the main hotel, on which they might depend for their meals, but which cottages should be so arranged that they could keep house in them if they so desired. I hope that our health resorts may gradually approximate those of Europe in comfort and luxury, so that our patients will no longer look forward to a visit to those of Europe with pleasure, and to a visit to our own as a kind of banishment to be endured for the sake of health.

And now let me say one word about the management of the association. If a narrowing of the field of labor is good for us, so also is the limitation of the responsibility of running the society. It is of no use to try to manage the routine business by means of a committee composed of men residing, perhaps, at long distances from each other. The one-man power is what is wanted. We want a man to run the association who is elected for a term of years, or, better, perhaps, who is re-elected from year to year, unless there is some objection to him. This officer can best be the secretary and treasurer, as he keeps the minutes, and naturally has the best knowledge of the affairs of the association. He should be constituted executive officer of the association, and be expected to make preliminary announcements, secure papers and the attendance of members, get up programmes of the meetings, and, in fact, make every meeting a success.

Without such a head we shall fail. When you can find a good man to undertake this work, don't resent being "bossed" a little by him, but let him have what glory there is in running the association, for he will have earned it. The place of meeting will naturally come before you for discussion, and, while not wishing to anticipate the discussion, I can not help expressing my feeling that, inasmuch as it is very desirable for us to have at our sessions representatives from all parts of this country, especially from the far West and South, we shall be able to secure this best by frequently meeting at the same place with the American Medical Association.

And now, after these brief, desultory remarks in the way of an introduction, let me bring you, without further delay, to the regular papers of the day.

THE INTERNATIONAL CONGRESS FOR HYGIENE AND DEMOGRAPHY.—Besides the International Medical Congress at Copenhagen in August, the International Congress for Hygiene and Demography will assemble for the fifth time, from the 21st to the 27th of the same month, at the Hague. Judging from the programme, which has been published at great length in the French medical journals, many papers of the highest interest are likely to be discussed, among them, one by Dr. Pasteur, on "The Attenuation of Virus"; on "Temperature within the House," by M. Emile Trélat; on "Water Supply," by Dr. Crocq, of Brussels; and "Science the Enemy of Disease," by Professor Corfield. The first section will be devoted to general and international hygiene; the second, to that of towns and rural districts; the third, to personal, and the fourth, to professional hygiene. Information may be obtained from Professor Overbeck de Meijer, of Utrecht, the general secretary.—*Medical Times and Gazette*.

Original Communications.

THE TREATMENT OF EPILEPSY.*

By LANDON CARTER GRAY, M.D.,

PROFESSOR OF NERVOUS AND MENTAL DISEASE, NEW YORK POLYCLINIC; PHYSICIAN-IN-CHIEF TO THE DEPARTMENT OF NERVOUS AND MENTAL DISEASE, ST. MARY'S HOSPITAL, BROOKLYN.

I HAVE been surprised, in passing among medical men, to learn of the prevalence of the belief that the treatment of an epilepsy is either useless or only temporarily beneficial. Had this opinion been confined to the ill informed smatterers who saunter into every calling, and who can be found upon occasion even in our learned profession, I should not have wondered; but I have also found it largely among earnest, honest, well-read practitioners, whose knowledge of general medicine and surgery was fairly equal to the emergencies of their career. Yet it was, as is usually the case, pure lack of reflection that made me feel surprised. Neurology is the latest of all the specialties. Ten years ago but a few colleges in the United States had any systematic course of instruction in nervous disease; and even today, while gynecology, for instance, is made to rank in importance with midwifery, and graduates go forth flourishing a speculum with a nonchalance that has been bred in many lectures and many operations, the broad and complex study of mental and nervous phenomena is relatively disregarded, unless the eminence of some particular lecturer should gild his specialty with a local splendor. Only lately has it been, moreover, that text-books upon the subject have been sufficiently salable to kindle the desire of publishers. Probably, too, great as has been the development—almost entirely in Germany and France—of knowledge in the anatomical, physiological, and pathological aspects of neurology and psychiatry, made with such scientific elaboration and deliberation as have been rendered possible by magnificently endowed and equipped institutions of learning, enough time has not elapsed to naturalize the specialty in England and America for the utilitarian and therapeutic purposes which are more in consonance with Anglo-Saxon habits of race and social organization. The physician, therefore, who, uninstructed at the start, has left a medical school to plunge into the active duties of practice, has not had conveniently at hand the wherewithal to supply him with the well-sifted information which he can readily obtain upon other professional topics. I have consequently been led to conjecture that a paper upon the treatment of a disease so baneful and so frequent as epilepsy would be of interest to many, and possibly also of service, should the modifications and regulations which clinical experience has taught me to make in regard to many familiar details prove as timely as I have fondly believed them to be.

There are certain peculiarities about epilepsy with which one should be acquainted before justifiable deductions can be drawn from any method of treatment, and these have been almost entirely overlooked by authors.

* Read before the Medical Society of the County of Kings, May 20, 1884.

In the first place, epilepsy is a very mobile disease. By this I mean that it reacts very readily to impressions made upon it, whether those impressions travel to it from the stomach, along the nerves of general or special sensation, or from the cortex of the cerebrum. Almost any change of treatment will produce a temporary effect. Hence it is that so many remedies have been vaunted for its cure. Hence it is that M. Brown-Séquard thought he obtained better results after adding the bromide of ammonium or the bromide of sodium to the bromide of potassium, just as Dr. E. C. Seguin has lauded the addition of chloral hydrate to the bromide of potassium. Hence it is that trephining, removal of cicatrices, operations upon the male and female genitals, and nerve-stretching, have brought a seeming success for the time being, and interjected so many false data into our therapeutics. I am somewhat given to referring to the case of a chronic epileptic in one of our city institutions who, being subject to convulsions every few days, fortunately fell into a tub of hot water, burnt himself severely, and had never a fit for upward of a year. After I had been teaching this mobility of epilepsy for some time, I came across the following passage in Esquirol's great work, showing that the fact had been familiar to him, although it would seem to have escaped the attention of all other writers upon the subject: *

"I have treated three hundred and eighty-five women or girls, of all ages, past puberty, belonging to the poorer classes. Of this number, forty-six were hysterical and three hundred and thirty-nine epileptic; the majority were more or less chronically insane. . . . I desired to test the efficacy of the most varied remedies. I tried successively blood-letting, purgatives, baths at every temperature, issues, the caustery, moxas, antispasmodics—both vegetable and mineral. I stopped with hydrocyanic acid. I procured or bought the secret remedies. Every spring and every autumn I chose thirty epileptic women with whose disease I was best acquainted, as regarded the past, the causes, and the symptoms. These women were prepared in advance by exciting their imagination by the repeated promise of a certain cure. I was efficiently seconded by the nurse and the internes. In all cases a new medication suspended the attacks during fourteen days in some, during one month or two in others, and even three months. After this period the attacks reappeared successively in all the women, with the characteristics which they had presented for years before. Several of our epileptics were subjected to my experiments for years; but I must confess that I was unable to obtain a cure. In my private practice I have been scarcely more fortunate; if the attacks were suspended, it was less from the action of the medicaments than from the effect of the confidence which led the patient to consult a new physician. . . . Authors have mistaken for cure the spontaneous suspension of the attacks, or their suspension by the action of every new remedy; the error is the more possible because the patients are lost to the sight of the physician, who is not consulted upon the return of the paroxysm."

And then this thoughtful and patient student of diseased nature cites a number of cases in support of his views. Among them this one, which may be *apropos*:

"The Prince of —, epileptic since early youth, would permit no one to wait upon him, in spite of the entreaties of his family. With the progress of age the attacks became more fre-

quent; when fifty-seven years old, the Prince was taken with a paroxysm, during which his head fell into the fire. The burn, charring the scalp, penetrated to the external table of the parietal bones. An abundant suppuration was established. The wound was kept open by a bit of necrosed bone. The patient, becoming impatient, sought the aid of a surgeon, who removed the bony fragment, when the cicatrization proceeded rapidly, and was completed in forty-two days. During this time the patient had no attack, but immediately after the healing of the wound the fits recommenced."

Epilepsy is very often quasi-periodical. The ensuing cases will best illustrate my meaning:

K. T., aged fifteen, girl. Grand mal for two years. Attacks about every six weeks, *always, with two exceptions, between 7 and 8 A. M.*

E. G., male, aged twenty. Grand mal for eighteen years and a half. Attacks daily, *always, with three or four exceptions, upon rising from bed in the morning.*

R. C., aged nine, female. Grand mal over a year. Fits several times weekly, *invariably between 11 P. M. and 7 A. M.*

P. S., aged eleven, female. Grand mal for over a year. Attacks generally once in the month, occasionally twice, *always about 7 A. M.*

W., aged thirty, female. So-called "Jacksonian epilepsy" for fifteen years. *Twitchings always between 12 P. M. and 4 A. M.*

D. M., aged forty-one, male. Grand mal for three years. *Attacks always between the seventeenth and twenty-fifth of the month, and always between midnight and breakfast time.*

Female, aged nineteen. Grand mal for six years. Attacks at the menstrual period, generally about the first of the month.

Male, aged twenty-nine. Fits always one half to three quarters of an hour after rising in the morning.

Male, aged twenty-five. Fits about the time that the moon is becoming full.

Male. Has had three fits, each about eighteen months after the preceding one.

In what proportion of cases this quasi periodicity occurs I am, unfortunately, not able to say, since the cases in which I have sought it, and in which the memory of the patient or the patient's friends has been reliable, have not exceeded forty, a number too small for a scientific deduction of this kind. Of this forty, however, nine manifested these symptoms. I regard it as scarcely necessary to state that I have always carefully excluded malaria as a possible cause of this quasi periodicity.

Epilepsy is often inter-convertible with migraine; that is, a migraine will often have its place taken by an epilepsy, and *vice versa*; and, in individuals hereditarily or personally predisposed to epilepsy, migraine will often precede the graver disease by months or years. I am inclined to believe that the majority of patients with migraine will have occasional losses of consciousness, attacks of great dizziness, or other nervous symptoms that are of a graver type than the mere migraine.* While these facts are not unknown to

* By migraine I mean that form of headache, usually unilateral, which recurs in certain individuals at regular or irregular intervals and lasts from twelve to twenty-four or thirty-six hours, occasionally even longer. It is to be distinguished from neuralgia by its relatively short duration, by the persistence of these recurrences through years, by the prostration attending it, usually profound, by its gradual increase to a culmination which is characterized by severe, generally agonizing pain, and also, as a rule, by emesis.

* "Maladies mentales," etc., Paris, 1838, t. i, p. 136.

neurologists, they may be new to many of my readers, and the ensuing histories may be pertinent:

Male, aged forty-five. Has had migraine since he can recollect. Two sisters subject to it. Four years ago began to have epileptic convulsions—grand mal. Became rapidly worse; developed occasional attacks of furor epilepticus, and is now a hopeless epileptic, dangerous at all times because of certain fixed delusions, and uncontrollable when the mental aberration appears.

Female, aged fifty-three. Migraine for five years. During last year has had, toward the latter end of the attack, violent movements of the muscles of the trunk, so that the body is violently straightened up into an erect attitude.

Female, aged twenty-three. Been subject to migraine ever since she was a little child, coming on once or more weekly. Has lately, since birth of last child, become, temporarily, almost blind during these headaches. Father was subject to migraine. For the last week has had attacks of "fainting," in which she does not entirely lose consciousness, but is unable to move. These come on suddenly, without apparent cause, and have greatly alarmed her.

Male, aged thirty-six. I know nothing of the hereditary history. Has been for many years subject to severe and well-marked migraine. In last two years has had two attacks, consisting of sudden loss of consciousness, so complete that patient fell, injuring himself, and had no recollection afterward of the occurrence.

Female, aged thirty-four. One sister was an epileptic and was insane for some years before death. Mother died of apoplexy. All her life subject to migraine, generally severe in character. Has repeatedly, while the headache is upon her, lost consciousness of her surroundings, so that several hours remain a blank to her; and she has, upon a few occasions, been mildly maniacal immediately after a headache—i. e., after the culmination in emesis has taken place and the pain has become bearable.

Female, aged about forty. Subject to migraine since childhood. Latterly has had epilepsy, grand mal mainly, occasionally petit mal. Has been coming to my clinic for some two years. Whenever her epilepsy grows worse, the migraine improves, and *vice versa*. One alone being treated, the other grows worse. When both are treated, she goes for long periods without fits or headache.

From a prognostic point of view, however, there is a vast difference between these epileptiform attacks occurring in migraine and true epilepsy. The baneful effects of true epilepsy upon the mental structure are familiar to us all. The gradual weakening of all those delicate and only peripherally describable mental manifestations which lift a human being to the higher planes of intelligence and constitute what we English-speaking peoples have agreed to call "character"; the gradual passage into absolute dementia; the supervention of convulsions or attacks of *petit mal* that seriously interfere with the active businesses of life—all these, which are so frequent in true epilepsy, are very infrequent in migraine. Fortunate, indeed, is it that this is so, for migraine is a very widespread disease, and scores of the most active and useful human beings among us are the bearers of it. If I were at liberty to do so, I think I could read off a startling list of names of sufferers to be found in many different walks of life in this city of Brooklyn. Perhaps I can give you a better idea of how I

have come to regard migraine if I tell you where I classify it. I regard epilepsy as a nervous disease of very serious import to the mind, and, at times, to the general nervous system. I regard neuralgia as a nervous disease localized in one nerve or one set of nerves, and whose prognostic importance is usually only that of the pain which is produced. I place migraine midway between epilepsy and neuralgia—a localized neurosis, so to speak, or a neuralgic neurosis, or a neurotic neuralgia. Most cases remain midway between epilepsy and neuralgia, manifesting more severe symptoms than a mere neuralgia, but yet not so severe as those of epilepsy, occasionally, however, when the attacks are more frequent or more painful than usual, manifesting epileptiform symptoms. This is the type. But many cases approximate more nearly in character to neuralgia, frequently differing from it for years only in the relatively short duration of the attacks, the irregularity and often the suddenness of their onset, the tendency to commence as a vague feeling of weariness or unrest, generally in the morning, the culmination, in a few hours or toward night, in sharp pain, with or without nausea, and the relative triviality of the causation, such as moderate fatigue, a change in the barometer or thermometer, some passing emotion of more than ordinary intensity, some slightly unusual excitation of a special sense, as a disagreeable odor, straining of the eyes, etc. Finally, there are some quite exceptional cases in which the symptoms partake strongly of the epileptic character, or else the migraine actually becomes inter-convertible with true epilepsy, as in the cases which I have narrated. I have, therefore, called attention to this kinship between migraine and epilepsy, not so much on account of the prognostic aspect of the matter—although, as we have seen, that can not be entirely disregarded—as because of the therapeutic considerations, of which we shall take account further on.

The frequency of epileptic fits varies enormously in different persons and at different times, as is shown by the history of a number of my cases, taken at random from among those in which the course of the disease had not been altered by treatment, so far as I have been able to ascertain:

1. Fits about every six weeks. Duration two years.
2. Before six years ago only one or two fits yearly; lately once weekly, occasionally two weekly; sometimes goes over the month; once free for nine months while at the clinic, while under treatment with the bromides. Duration eighteen years.
3. About once in three weeks. Duration four years.
4. Several weekly. Duration one year.
5. Three or four daily for the first three months; since then once weekly or biweekly. Duration four years.
6. Duration six years. Formerly two or three daily; now once monthly, about the menstrual epoch.
7. Duration about two years. About one weekly.
8. Duration six years. For three years, four or five monthly; during next two years, one or two yearly; in last year, two.
9. Duration ten years. Second fit about nineteen months after the first; third, eighteen months after; next, after one year's interval; then for some time—not more definitely stated—about three to four months; then none for fifteen months; since, about once in three or four months.
10. Duration twenty-nine years. At first three fits in six

weeks, then none for ten years; but muscular twitchings, without any loss of consciousness, often several times in the week; then seven violent fits in succession; was unconscious several hours; then none for three years, but twitchings; for next five years, one every two to three months; no fit for six years, but twitchings; for two years one every two months; in last three years about four fits, but no muscular twitchings.

11. Duration fourteen years. About three monthly.

12. Duration about four years. Fits vary in number from one weekly to seven daily.

13. Duration about one year. At first about two weekly; then free for seven months.

14. Duration two years and a half. Never two weeks without them; occasionally several in a week.

15. Duration fifteen years. About one a month.

16. Interval between first and second fit over five years; interval between second and third fit, fifteen years; then about two monthly; then once in four or five months; eight in the last thirteen months.

The periods of time that elapse between the first and second fits are extremely variable, extending, at times, over years. Thus Gowers* has analyzed 160 cases with the following results:

Interval between the First and Second Severe Fit in 160 Cases of Epilepsy.

Less than 1 week.....	18	55 cases under one month.
1 week to 1 month....	37	
1 month to 3 months..	13	
3 months to 6 months..	21	52 cases more than a month and less than a year.
6 months to 1 year....	18	
1 year to 2 years.....	18	
2 years to 3 years.....	6	53 cases more than a year.
3 years to 5 years.....	7	
Over 5 years.....	22	

Viz:

6 years.....	3 cases.
7 years.....	9 cases.
8 years.....	1 case.
10 years.....	3 cases.
11 years.....	1 case.
14 years.....	1 case.
16 years.....	1 case.
18 years.....	2 cases.
20 years.....	1 case.

"According to these figures," continues the author, "in one third of the cases the second attack occurs within a month; in another third it is postponed until after a month, but occurs within a year; while in the remaining third more than a year elapses between the first and second fit. I think it probable that these figures exaggerate the relative frequency of prolonged intervals, since in such cases the facts are more likely to be noted; but they serve, at any rate, to show that the risk of a second fit remains considerable for at least twelve months after the occurrence of the first fit, and that, although it rapidly falls after the second year, it does not practically disappear until after ten years have passed, while cases are occasionally met with in which a still longer period—fourteen, sixteen, eighteen, and even twenty years—elapses."

What prognosis are we, then, to give in such a case as the ensuing one?

T. C., aged nineteen, house painter. Had a fit the night before coming to me. Attributes it to the fact that he had been masturbating the day before. While walking along the street, looking at some painters, he suddenly saw before him rings revolving, which grew smaller and smaller, when he lost consciousness. Was told that he foamed at the mouth and gripped his hands together. Afterward slept about four hours. Has been a masturbator for the last five years. Never had a fit before. No signs whatever of any renal trouble, which was carefully sought for by chemical and microscopic tests, nor any ascertainable organic disease. As he had a phimosis, I circumcised him. This was over five years ago, and during this time he has had no other fit.

The waning school of enthusiasts, who fondly regard genital irritations as the fertile source of all diseases in which there is a possibility for diagnostic error, will, no doubt, explain this prolonged immunity in accordance with their darling theory; but the figures which I have just read will not permit of any such hasty conclusion. Time alone can tell whether this patient is to have another convulsion. For aught we can predict to the contrary, he may, like Gowers's patient, have another convulsion twenty years after the first.

The thought would naturally suggest itself that we might, by careful analysis of a sufficient number of cases, be able to formulate some law in this matter of intervals between the fits, and thus build up a system of averages. Gowers, indeed, believes that he has done this. But his tables attest the truth of the time-worn saying, which has been imputed to Sidney Smith—and which would have done him no discredit either—that nothing is more unreliable than facts, except figures. In these tables the cases are divided into those in which the interval does not exceed one day, those in which it is more than one day but not over one week, those in which it is over one week but not exceeding two weeks, etc., and the number of cases in each class is then ascertained, when, of course, it is a simple matter to compute the percentage of each class to the whole. If my reader will take the trouble to run over the cases in which I detailed the intervals, or, far better, if he is familiar with epileptics, he will readily appreciate that one and the same epileptic may have intervals varying so greatly in length of time as to put him, if he lives only a few years, into every one of the eight classes which Dr. Gowers has so uselessly constructed. I fail, therefore, to see how it is possible to obtain any averages in so capricious a disease as epilepsy, unless a large number of patients can be kept under observation for periods of ten years and more, without the disturbing influences of treatment of any kind. This is, of course, impracticable in the ordinary forms of the disease, such as are relatively amenable to treatment, and can only be carried out with those hopeless wretches who are huddled into our public institutions.

It is very much the custom to pay slight attention to convulsions occurring in young children, and to easily dispose of them by attributing their causation to some coincident, or precedent, or ensuing phenomena—as dentition, indigestion, etc. Indeed, one recent writer* has advanced

* "Importance of the Early Recognition of Epilepsy," E. C. Seguin, M. D., "Med. Record," Aug. 6 and 13, 1881.

* "Epilepsy," London, 1881, p. 190.

the axiom that convulsions after the third year are very probably epileptic, while, under the third, any such attacks are probably eclamptic. There seems to me to be great fallacy in these terms and these conclusions.

(To be concluded.)

NOTES ON HOSPITAL TREATMENT.*

I. The Night-Sweats of Phthisis.—II. Pyo-thorax.

By DR. B. F. WESTBROOK,

PHYSICIAN IN CHIEF TO THE DEPARTMENT OF DISEASES OF THE CHEST, ST. MARY'S GENERAL HOSPITAL, BROOKLYN, N. Y.,

AND DR. ISAAC HULL PLATT,

ASSOCIATE PHYSICIAN TO ST. MARY'S GENERAL HOSPITAL, BROOKLYN, N. Y.

I. *The Treatment of the Night-Sweats of Phthisis.*—At St. Mary's Hospital, during the last year and a half, some attention has been paid to the treatment of the night-sweats of phthisis, with results which are thought worth reporting, although still incomplete.

The treatment employed in the earlier cases was the administration of ergotin and quinine, in doses of one grain each, in pill form, every three hours.

The first case that the hospital notes show was that of a girl, nineteen years of age, in an early stage of phthisis with profuse night-sweats. She was admitted November 30th, and remained under observation till December 14th, during which time she was subjected to the above-mentioned treatment, with the result of great diminution, but not entire cessation, of the sweats.

The second case reported is that of a woman, aged thirty-eight, with phthisis of four months' standing and very profuse sweats. On December 20th she was placed upon this treatment. The sweats gradually decreased till January 1st, when they were very slight, and continued so until about February 1st, except on three occasions, when, the pills having been omitted through the day, during the following night the sweating was again profuse. From the 1st till the 17th of February the sweats gradually increased again, despite the continued administration of the pills, and by the latter date they were nearly as bad as ever.

The hospital notes show a number of cases of a similar nature, in all of which, under the influence of the ergotin and quinine pills, there was either a great diminution or entire cessation of the night-sweats, lasting for periods varying from one to three months. In only one case did they fail to exert a marked influence over the symptom. As a rule the pills were well borne, producing little or no gastric disturbance.

Picrotoxin is the drug which has been used in the greatest number of cases.

The first case in which it was used was one in which the ergotin and quinine had controlled the sweats for a month, and which had subsequently been treated with quinine and zinc sulphate, and with small doses of Dover's powder, without apparent effect, and in which atropine was tried, with the result of reducing the sweats, but also of producing such annoying dryness of the throat as to preclude its continued use.

The picrotoxin was at first administered in the dose of $\frac{1}{16}$ of a grain hypodermically at night. The first injection was given on March 24th; the following night the sweating was less, and

on March 27th it had ceased entirely; from that time till April 3d there was no sweating, the picrotoxin being administered every night. By this time, April 3d, the sweats had recommenced slightly, and the dose was increased to $\frac{1}{8}$ of a grain at night. From this time till May 1st, twenty-seven days, there was no sweating, except on two occasions, when the picrotoxin was omitted and a slight sweat followed.

From May 1st to May 10th medication was suspended, with the result that the sweats gradually increased in severity until the latter date, when they were as bad as ever.

From the 10th to the 26th of May picrotoxin was given in doses of $\frac{1}{16}$ of a grain hypodermically every second or third night, with the result of controlling the sweat entirely for two nights following its administration; the third night, if none was given, there would be a slight sweat.

In a subsequent case the dose of picrotoxin was increased and the interval between the doses lengthened until it was found that $\frac{1}{16}$ of a grain hypodermically at night would control the sweats for ten nights following.

In other cases the picrotoxin was given, either hypodermically or by the mouth, at intervals varying from two to ten days, and in doses of from $\frac{1}{16}$ to $\frac{1}{8}$ of a grain.

The total number of cases in which the drug was administered was nine; in six the sweats were entirely checked, in two they were greatly relieved, and in one very troublesome case it seemed to have no effect whatever.

The observations go to confirm the results of Murrell's experiments, who had but one failure in twenty cases, and found the effect to last about ten days, though we have found it necessary to use larger doses, he stating that he accomplished this result with from $\frac{1}{16}$ to $\frac{1}{8}$ grain.

In one case, where picrotoxin by itself only relieved the symptom, combined with quinine it completely controlled it.

II. *The Treatment of Pyo-Thorax.*—The objects to be accomplished in the treatment of a case of empyema are:

1. The removal of the purulent effusion.
2. The prevention of the decomposition of the pus, its absorption, and consequent infection of the system.
3. The promotion of expansion of the collapsed lung to as nearly as possible its original dimensions.
4. The promotion of adhesions of the walls of the suppurating cavity, the obliteration of the cavity itself, and the prevention of the forming of sinuses and pockets with the consequent continuance of suppuration after apparent recovery.

The surgical treatment of empyema, which is the only treatment of any value as a curative measure, may be classed under two heads, namely, the close and open plans. The first consists in simply tapping the chest by means of a trocar and cannula, or with the aspirator. This meets the first indication, that of removing the pus, and, especially if the aspirator is used, there is very little danger of the entrance of air into the pleural cavity and the consequent decomposition of the pus.

To Trousseau is due the credit of first insisting upon the performance of paracentesis in all cases of empyema. His views were warmly seconded by Dr. Bowditch, of Boston, in 1852, who demonstrated the harmlessness of the operation by its use in several hundred cases of serous and purulent effusions without the loss of a single patient as the

* Read by Dr. Platt before the Medical Society of the County of Kings, May 20, 1884.

direct result of the operation. Previous to this time the greatest reluctance was felt toward any surgical interference whatever. At present the opinion of the profession seems to be nearly unanimous that operative treatment of some kind is called for in almost every case of empyema. Berger, in the "*Union médicale*" for January 1, 1884, says in every case except those complicated with either tuberculosis or amyloid degeneration, in which he regards the prognosis as too hopeless for operative interference to be of any value.

In the latter of these complications, Dr. Kretzschmar and Dr. Westbrook have demonstrated that operation is not necessarily hopeless by the case reported to the Medical Society of the County of Kings in December, 1880, where, in a girl with the most marked and positive evidence of amyloid degeneration of the liver and kidneys, Dr. Kretzschmar opened the thorax by a free incision and evacuated a large quantity of fetid pus, which proceeding was followed by gradual improvement and complete restoration to health within a year. This was over four years ago, and the patient is still well and strong.

In cases of empyema the close plan of treatment, or paracentesis, falls short of a curative measure for the reason that in a vast majority of cases the pus is quickly formed again, and the value of the operation is therefore limited to that of a palliative; in illustration of which may be instanced a case, reported by a correspondent of the "*British Medical Journal*" in 1882, of a boy seven years of age, whose thorax was aspirated five times in thirty-five days, 200 oz. of pus being removed altogether, with temporary relief following each operation. The treatment was finally abandoned, and prompt relief followed free incision. Numerous similar cases are reported, and occasionally one where a permanent cure is effected in this way, but in the vast majority of cases more radical means have finally to be resorted to.

The first and most obvious form of the open treatment was that of making a free incision in an intercostal space, evacuating the pus, and introducing a drainage-tube.

The experience of most surgeons with this form of treatment has been that sufficiently free drainage can not be obtained, both for the reason that there is not sufficient room in an intercostal space, especially after the sinking in of the chest-wall following the evacuation of the pus, and because of the rapid growth of granulations about and occluding the opening, making the removal and replacing of the drainage-tube a very difficult and painful proceeding, in many cases only to be accomplished by continual division of the fistula with tents, enlargement with the scalpel, etc. This renders the operation so unsatisfactory as to lead to a great number of modifications, some of which will be briefly considered by way of introduction to the report of three cases treated at St. Mary's Hospital during the last year, with, in the main, satisfactory results.

The method devised by Chassaignac for meeting this obstacle is to make an incision in the anterior part of the thoracic wall, and, passing a probe through the pleural cavity until it impinges upon the posterior wall, to cut down upon it and pass a long drainage-tube through the two openings, by means of which the cavity can be freely irrigated. Two interesting cases treated by this method are re-

ported by our friends, Dr. Conway and Dr. Thallon, in the "*Archives of Medicine*" for February of the present year, with the result of cures in from two to three months.

This is the favorite proceeding with British practitioners, and is, undoubtedly, the most satisfactory in its results of all methods which seek to obtain drainage through the intercostal spaces only. It is strongly advocated by Dr. De Havilland Hall in "*St. Bartholomew's Hospital Reports*" for 1876, the methods by resection of a rib, to be hereinafter mentioned, being considered by him to be unnecessarily severe.

Dr. Fraentzel, in his article in von Ziemssen's "*Cyclopædia*," advocates a method of his own. It consists in a free incision in the fourth or fifth intercostal space, and the introduction of two soft-rubber catheters, through one of which a stream of warm carbolized lotion is thrown in until the return flow from the other catheter is perfectly clear. The catheters are then removed, and a silver cannula, with a collar to prevent its slipping into the cavity, is introduced into the wound, and through this, by the aid of the two catheters, the cavity is washed out daily, as in the first instance. In the "*Lancet*" for March 5, 1881, two cases are reported of treatment by this method, resulting in recovery, in the first instance in three months, and in the second in five months.

Lister's method is a modification of Fraentzel's, and may be found detailed in the "*Lancet*" for 1879. It consists of a free opening into the chest under the spray, and with full details of Listerism, and, after a thorough washing out of the pleural cavity with an antiseptic solution, the introduction of a metallic tube with a collar to prevent its falling in, and with its inner extremity rounded and perforated with small holes. The wound is then covered with the Lister dressing, which is to be left until the discharge shows itself through the dressing, or some other indication calls for its removal.

The advantages claimed for this treatment are: 1. Free drainage. 2. The prevention of decomposition of the pus. 3. It causes less disturbance than frequent irrigation. 4. It produces no irritation of the pleura. 5. One cause of sudden death—namely, that of shock from throwing fluid into the cavity—is avoided. It seems difficult, however, with this arrangement, to see what is to prevent the holes in the drainage-tube from becoming plugged with flakes of lymph and membrane.

An ingenious method of obtaining continuous irrigation of the pleural sac, as well as of excluding the air therefrom, is reported in the "*Lancet*" for 1881, by the enterprising house surgeon who devised it.

The pleural sac being first filled with the disinfectant fluid, one end of the long rubber tube was passed into the intercostal incision and retained by some means which prevented the air from passing around it. The other end was carried down through a hole in the mattress into a bottle filled with a warm disinfectant solution, Condyl's being preferred, which was changed every hour, the fluid in the tube rising and falling with each inspiration.

In the "*Transactions of the Medical Society of the State of New York*" for 1880, p. 332, Dr. A. M. Phelps, of

Chateaugay, N. Y., suggests a method of treatment which in his hands has been followed by good results. It consists in making two openings into the chest, anteriorly and posteriorly, as in Chassaignac's method, both in the lower portion of the pleural cavity. The anterior opening is made with a trocar and cannula, and the cannula allowed to remain in the wound. The posterior opening is also made with a trocar and cannula, they being first passed through a small sheet of rubber which is attached to the chest-wall with strips of adhesive plaster, the cannula being provided with a valve opening outward, and a dependent rubber bag to catch the secretion. Irrigation is accomplished by attaching a rubber tube and funnel to the anterior cannula, and washing through until the fluid discharged through the valved tube is perfectly clear. The anterior tube is then plugged with a piece of wood, the valve preventing the entrance of air by the posterior opening.

This completes the consideration of the principal methods of obtaining drainage through the intercostal spaces. It remains for us to consider the various means for obtaining greater space for this purpose, and thus promoting this most essential requisite in the treatment of these cases—namely, good drainage.

In order to meet this indication, Dr. Peitavy, of Berlin, removed about one inch of the seventh rib after unsuccessful attempts to keep open an intercostal fistula. The patient made a good recovery, and the treatment has been followed with good results; but the operation was improved by Langenbeck, in a case reported in 1869. He adopted the plan of removing with a trophine a semicircular piece from the upper border of a rib. In this way he avoided the wounding of the intercostal vessels and nerves, and obtained a sufficiently large opening for drainage, and one with bony walls which could not easily close.

The perforation of a rib in a manner similar to this is said to have been recommended by Hippocrates, and to have been practiced by his followers, and there seems to be some reason for attributing its introduction into modern surgery to Reybard. The operation is commended by a large number of French and German surgeons, and is the one adopted in the cases which furnish the text for this paper. The case reported to this Society last year by Dr. Harrigan, where Dr. Wight removed a small piece of bone from the center of a rib in a child by means of a dental engine, was on a like principle.

An obstacle to permanent relief in some cases, especially those of long standing, is that the parts become so fixed in their new relations that the cavity does not become entirely obliterated, but pus collects in pockets and sinuses in the more dependent portions of the pleural sac, or, even if it is all removed, the cavity not being entirely obliterated, the pus will form again after apparent recovery. This state of things is illustrated by one of the cases to follow.

To obviate this difficulty, various expedients have been devised, such as strapping the chest, applying a bandage to the abdomen for the purpose of forcing up the diaphragm, daily forced inspiration, etc.; but the most thorough and radical method, which at present stands as the last resort in troublesome cases of pleural pus cavities, is the thoraco-

plastic operation of Estlander, which consists in removing a portion of one or more ribs—as many as may be necessary—for the purpose of allowing the costal wall to fall in and obliterate the cavity by adapting itself to the surface of the lung.

In Langenbeck's "Archiv" for 1881 are reported 141 cases of this operation, with 46 per cent. of cures, 33 per cent. of deaths, and 21 per cent. left with fistulous openings. Fifty-two of the operations were performed under strict antiseptic precautions, and in these, 50 per cent. of the patients recovered and 17 per cent. were left with fistulous openings, the mortality being the same as in the total number, 33 per cent. Berger and his *confrères*, in the "Union médicale" for January 1st of the present year, and the following numbers, report 27 cases treated by this method, with the following results: 10 patients were completely cured, 5 were greatly improved, 3 were unimproved, 4 died, and 5 were lost sight of after some improvement.

Norman Porritt, in the "Fothergillian Prize Essay" of 1883, recommends resection of ribs in cases which have withstood treatment for more than six months after the first incision.

An interesting point in the history of this operation is that it appears to have been suggested and used by an American surgeon so long ago as 1858. In the "British Medical Journal" for January 21, 1860, Dr. Albert G. Walter, of Pittsburgh, Pa., reported the following case:*

A river-man, thirty-two years old, of strumous diathesis, was stabbed in the left side between the eighth and ninth ribs, one inch posterior to the mid-axillary line. On the ninth day an abscess pointed below and anterior to the wound, which had closed. After a few months the opening closed, but soon the original wound opened again. He had the appearance of confirmed phthisis, hectic, etc. Daily irrigation with tincture of iodine was tried, but proved of little avail.

On December 8, 1857, a crucial incision was made and an inch of the eighth rib was removed. He improved markedly, and the hectic disappeared. Tincture-of-iodine injections were resumed, but discontinued, as they produced chills and irritative fever. He grew worse again, and, on February 11, 1858, two inches of the eighth and ninth ribs were resected. The thorax was then more freely examined than it had probably ever been on the living subject by any observer previously, and the suppurating surface destroyed with a spatula and the finger-nail. The cavity extended from the diaphragm to the middle of the scapula, and would have admitted the head of a child one year old. The opening closed in four months.

Fever soon returned, and the fistula reopened. The cavity was washed out with tincture of iodine on a sponge, and then syringed with water. Afterward a wash of caustic potash, 3j to a pint of water, was injected. This produced soreness, enlargement of the fistulous opening, and discharge of large flakes of pseudo-plastic membrane. Injections were continued till the flaky matter ceased to be discharged, and then a decoction of white-oak bark was used, with occasional syringing with compound tincture of iodine. The fistula was kept open by the daily introduction of a bougie, and finally, the discharge having ceased, the external opening was allowed to heal during the early part of January, 1859. Three months later the patient was discharged well. The left side of the chest measured an

* For a reference to this case the authors are indebted to an editorial article in the "Medical News" for March 1, 1884.

inch and a half less than the right. He was directed to wear a leather strap around the lower part of the thorax.

There seems to be no distinction between this operation and that known as Estlander's, either in the proceeding itself or in the object for which it was instituted.

The following are the cases treated in Dr. Westbrook's service at St. Mary's Hospital:

CASE I was that of a woman about twenty-eight years of age, of unsound mind, so that a very complete history could not be obtained, but there was some evidence that about a month before admission she suffered a fall during an epileptic fit, and sustained a fracture of a rib on the right side. She had a history of pleurisy extending back three weeks.

At the time of admission her right pleural cavity contained fluid as high as the level of the sixth rib, which the aspirator showed to be pus, and extremely fetid. The same foul odor was given off from her breath, strong enough to odorize the whole room. Her pulse was strong at 100, temperature 102.5° F., respiration 28. There was indistinct amphoric breathing near the lower angle of the scapula.

Her condition grew worse for a few days after admission, the temperature mounting to 103°, with occasional chills and some turns of coughing and dyspnea, the cough causing the expectoration of large quantities of very fetid purulent matter.

On May 26th Dr. Westbrook cut down upon the seventh rib, and, with a trephine, removed a semicircular piece from the upper border, leaving the internal periosteum intact. This and the costal pleura were cut through with a bistoury, and about eight ounces of fetid pus allowed to escape. The finger, introduced through the opening, detected extensive adhesions between the walls of the pleural cavity. A drainage-tube was introduced, and a pad of marine lint applied. The upper border of soft tissue was held back by sutures attached to adhesive plasters.

The patient took ether well and suffered no shock. In the evening her temperature had fallen to 99.75°. The cavity was washed out morning and night with a two-per-cent. solution of carbolic acid. On the second day after the operation, after the morning irrigation, she was attacked with a severe fit of coughing, with rapid breathing, and on the following day had developed a severe attack of bronchitis, with a temperature of 103° at night.

The bronchitis subsided in a few days, and by the seventh day after the operation there was a marked diminution in the purulent discharge, the foul odor had nearly disappeared, her temperature was normal night and morning, and she was gaining rapidly in strength.

On the seventeenth day the discharge had entirely ceased, the drainage-tube was removed, and the wound allowed to heal. Two months after the operation the wound was entirely healed and the patient well. There seems to be no doubt, from the signs and history, that this was a case of pyo-pneumothorax, the opening into the lung being probably caused by the fracture of a rib, the extensive adhesions preventing a great accumulation of pus.

CASE II.—A man, forty years of age, had an attack of pleurisy four weeks before admission. After two weeks from the commencement of the attack he began to convalesce, but grew worse again. His condition at the time of admission was very serious. He was very weak. The temperature at night was 103°, the pulse 108 and weak, the respiration 30. He had severe dyspnea, which became very urgent at night. The left pleura was full of fluid; the jugulars were distended and throbbing. About 6 oz. of healthy-looking pus were removed by aspiration.

On June 10th Dr. Dower opened the pleural cavity, trephining a rib, as in the previous case, removed about 40 oz. of healthy pus, and introduced a drainage-tube. The patient suffered very little shock. In the evening his temperature had fallen to 100.5°, the pulse was 120 and fairly strong, and he had no dyspnea.

In this case no fluid was thrown into the pleural cavity; the wound and end of the drainage-tube were merely covered with a pad of marine lint, into which powdered naphthalin had been rubbed, and this covered with Macintosh and changed daily.

The patient grew steadily better, the discharge diminishing in quantity, at all times being perfectly free from odor, and, in six weeks after the operation, had entirely ceased, the drainage-tube was removed, and in another month he was discharged cured.

These two cases are still under observation, twelve months having elapsed since the first operation and eleven since the second, and there has been no recurrence of trouble in either case. In each instance the lung expanded well, if not fully, and, beyond the evidence of thickened pleuræ, the physical signs are normal.

CASE III is that of a woman forty-two years of age. She did not come under observation until six months after the attack of pleurisy which resulted in the empyema. She was at the time of admission weak and anemic, with extreme dyspnea and very severe cough, with copious muco-purulent expectoration. The left pleural sac was evidently full of fluid, though two attempts to remove a portion with a hypodermic syringe were unsuccessful, owing probably to the great thickening of the pleura or viscosity of the pus. On the second day after admission, however, about three pints of thick but healthy pus were removed by the aspirator, which afforded some temporary relief to the dyspnea.

On October 17th Dr. Dower trephined the seventh rib and removed about two quarts of healthy pus. A drainage-tube was introduced, and the wound was covered with naphthalinated oakum and Macintosh.

The patient experienced great relief after the operation, and rapidly grew stronger, the cough and dyspnea at once disappearing. The cavity was not washed out, the dressing of naphthalinated oakum being changed at first twice a day and afterward daily.

Seven weeks after the operation the discharge had ceased and the tube was removed. At the end of the tenth week the wound had wholly healed, the patient was feeling well, and the lung had apparently well filled out, though the signs were somewhat masked by the thickening of the pleural membrane. She was discharged.

One month later she presented herself at the hospital with the history that she felt well for three weeks after going out, but for the last week had had slight chills and feverish feelings, and on the previous day the wound had opened and discharged about two quarts of fetid pus.

The pleural cavity was washed out with carbolic lotion, the wound being with some difficulty kept open. After a few weeks of treatment the discharge ceased, the wound healed, and the patient was again allowed to go home. Soon after the wound again opened and discharged, and the patient is at present at the hospital awaiting further operative procedure.

In regard to the first two cases, it will be observed that they were both of a very serious nature. The first involved an opening into the lung, with the pus in an advanced stage of decomposition. The second patient was so weak and exhausted that some doubts were entertained whether he

would live through the night previous to the operation, and, in fact, a quantity of the pus was removed during the night by means of the aspirator, to give him breathing room. Yet the first patient had entirely recovered in two months, and the second in two months and a half.

The incisions in all three cases were made in the mid-axillary line at the seventh rib. This proved to be sufficiently dependent in the recumbent posture to admit of good drainage, and saved the patients the annoyance of lying upon the wounds, as they would have had to do if the openings were situated farther back.

In the two latter cases, as there was no indication of fœtor in the pus, no fluid was thrown into the cavities, and the patients were saved the pain and annoyance of the daily irrigation, as well as the injurious effects on the pleural membrane, and the shock, which in a few cases has proved fatal, caused by the introduction of fluid into the cavity. It will be noticed that, in the first case where it was used, it apparently caused an attack of bronchitis.

The Macintosh, which was used in the second and third cases to cover the oakum pad, was intended not so much as an antiseptic precaution as to prevent the air from rushing into the pleural cavity through and around the tube with each inspiration, thus interfering with the due expansion of the lung. It rendered the breathing of the patients much easier.

It would seem very difficult, or well-nigh impossible, to exclude the air entirely from the wound and cavity, and in our cases it was not attempted; but, by its being filtered through the pad of naphthalinated oakum, the use of which Dr. Fowler introduced into the hospital, it was probably rendered very nearly or quite aseptic. It may be interesting to note here, in favor of the power alleged for naphthalin as a prophylactic against erysipelas, that during the treatment of the third case another patient in the same ward developed the latter disease, and the two patients remained in the ward together for fourteen or sixteen hours before the fact was discovered and corrected. No unfavorable result was observed in the patient with the open wound.

The third case was of six months' standing before coming under observation, and was evidently one of those where the parts are so firmly fixed in their new relation that it is impossible for the lung, bound down as it is by bands of adhesion, to expand and fill the cavity, and the only resource is Estlander's operation, previously described, which it is now proposed to do.

among its members many whose reputation is world-wide, and whose contributions are always sought for and read with interest. The volumes before us contain original papers, histories of cases, and descriptions of specimens illustrating rare and interesting forms of disease. The society was instituted in 1821, and it published three volumes of "Transactions," in 1824, 1826, and 1829. The papers submitted to the society during the next fifty-seven sessions (years) were never published in a collected form. We congratulate the society on the revival of its publications on the plan of issuing an annual volume, and hope the effort will meet with all the success to which it is entitled by the merit of the contributions.

LETTER FROM LONDON.

International Courtesy among Medical Men.—Post-graduate Work in London.—Mr. Thornton's Laparotomies.—General Surgery in London.—The General Plan of English Medical Education.—The English and the American Systems compared.

LONDON, June 14, 1884.

THE writer would deprecate the modern habit of English (and American) visitors, whether literary, scientific, or professional, of returning home and abusing their entertainers. The spirit of kindly criticism is one thing, but, until educated men and representative journals cease their polite *innuendoes*, there will remain, even in our own profession, that slight shade of mutual jealousy which crops out now and then in a most unpleasant manner. Suppose that an Englishman does snub you at the first interview; you discover in time that it is only "a way that he has," and he will be a trifle less frigid at each subsequent meeting. So soon as he finds that you are "all right" (and that you have not graduated from a bogus medical college) he will unbend considerably.

For the student a fortnight in London is far more enjoyable than a term of several months, but, on the other hand, he will be apt in the former case to carry away an erroneous idea as to the actual advantages to be derived from a lengthy stay in that medical center. It is unfortunate that Americans in general have not a clearer view of the English methods of instruction, and that they are so apt to compare them with the Vienna system.

For general work, the writer has no hesitation in advising the post-graduate student *not* to spend much of his time in England. The distances between the hospitals are so considerable, and the hours of work so arranged, that he will find he has accomplished very little in a day compared to the economical plan on which he has worked in Germany. Each hospital being an independent community in itself, and designed solely to meet the wants of its own students (who are often hardly conscious of the existence of any other), it is evident that an irregular worker must act at a great disadvantage.

Now, as the stranger is expected to matriculate at any hospital which he may attend regularly, and to be subject to the same regulations as the other students, it is unnecessary to explain how much he will be limited in his advantages. Most men would not care to attend a clinic simply by courtesy, but he must either do that or follow it in the capacity of an undergraduate.

Most of the practical instruction in the London schools is given at the out-door departments by the assistant surgeons, to whose zeal and ability we in America do not give half enough credit. Fortunately for English medical students (especially at examination time), some of the brightest minds of the profession are condemned to this limited sphere—limited, but *not* in usefulness.

As to courses for advanced students, such as are now provided in New York—we may dismiss these in a few words. Those

which exist are open to objection on the score of expense in money and in time, and are by no means so satisfactory as they might be.

For the special student London offers some advantages, yet none which can not be gained with less sacrifice elsewhere. In spite of the large amount of material furnished by such an institution as Moorfields or the Royal Ophthalmic Hospital, the advanced student can not use it with the same freedom as at home, and soon finds that he can employ his time to better advantage.

In gynecology there are indeed courses at the Soho Square Hospital, but their value to an American is doubtful. Perhaps the most valuable hints in that department are to be picked up at the Samaritan Hospital, where visitors are always welcome.

To one who has been accustomed to the fuss and confusion of German (and American?) operators, there is something very suggestive in the quiet and unostentatious manner in which Mr. Thornton and his *single* assistant perform their work. The expression "poetry of ovariectomy" might be properly applied to his beautiful operations. As to the results, it is unnecessary to speak. Those of the past year have been remarkable. Those who object to the troublesome details of a strictly antiseptic operation would be surprised to see what a simple affair it is in his hands.

Not to dwell upon a subject with which most of your readers must be familiar, it is enough to conclude with the statement that the practical lesson to be derived from a study of Mr. Thornton's work is, that no amount of dash and *élan* in a laparotomy can ever equal a careful, deliberate procedure, and the employment of every precaution which can insure the recovery of the patient.

As to general surgery, it may be said that a man can spend a week quite profitably in studying the peculiarities of different operators. But here, too, a certain amount of time must be lost, as many of the hospitals have their operations at the same hour. The American visitor will see not a few things to admire in the English methods, chief among which is the evident purpose of the surgeon to make his operation instructive to the spectators. We have special clinical lectures in surgery, yet our medical students frequently witness operations of the nature and purpose of which they have but a dim idea. This is not the case in the English hospitals, where every surgeon is a clinical lecturer, and every operation is thoroughly explained, as well as the pathological condition which makes it necessary. The practical benefit of this kind of instruction is unquestionable. As regards the operations themselves, the writer can state from his own experience that, even at one of the smaller hospitals, which he attended regularly, the number of capital ones was rather above our own average. Thus, there were three nephrectomies in ten days, all of which did well. Laparotomies are frequently performed in the general hospitals, and the patients generally make a good recovery. It is rather interesting to notice that the antiseptic (not Lister's) method in London is quite similar to that now in vogue in Vienna—viz.: irrigation with a carbolic-acid solution during the operation, and the free use of iodoform powder and salicylized jute in the dressings. The spray is pretty generally under the ban in ordinary surgery, unless, perhaps, in resections.

Reference has already been made to the character of the instruction at the English hospitals, and a more detailed account may be of interest. It is well known that the required course of study extends over four years, that a thorough preliminary examination is always required (in the absence of a degree), and that the course of study in the various schools is uniform, being designed to fit the students for the examinations which they must pass in common. The first two years are spent mainly in

the study of the elementary branches, especially anatomy, which latter, however, is never dropped as with us, but forms the framework on which is erected the entire structure. By careful, conscientious work in the dissecting-room (where a demonstrator is constantly present, and gives his *best* and not the fag-end of his time to the work), by dint of endless repetition in lectures, recitations, and demonstrations, the English student comes to have his anatomy literally at his finger-ends. Attached to each school is a carefully arranged museum of anatomical and pathological specimens, which is always open to him, and where he is encouraged to spend several hours each day. How strange that this valuable help is not recognized in America! And as with anatomy, so with every other branch of medicine, there is a constant purpose to make the instruction as thorough and practical as possible. Each school vies with the others in advancing the standard of education, and the students themselves seem to catch the healthful spirit of rivalry. To fail in their examinations is not only to disgrace their school, but to disappoint the instructors, who feel such a personal interest in their success. It is impossible for one who has not actually been connected with an English hospital to understand the peculiarities of the system. To the casual observer its only object seems to be a four-years cram, which shall enable a man to pass safely through the fiery ordeal of the College of Surgeons. The very purpose of that examination is to defeat such an object, and probably it succeeds as well as any examination could. The practical working is to be judged of by the results. It is enough to say that English medical students are, as a rule, educated gentlemen, and that is too often not the case with us—more's the pity.

Excuse the digression—we were speaking of the methods of teaching in the schools. The more advanced students have their daily hospital visits and bed-side instruction as with us (but more thorough and *personal* in its nature). Each case furnishes a subject for discussion before the class, and before it is disposed of the student who has it in charge is pretty thoroughly catechised. At the next visit the same subject is reviewed, and so on at each succeeding one, until it has become perfectly familiar to him. It is surprising how much time the visiting surgeons (men whose large metropolitan practice and years of honorable service might excuse them the labor if they so desired) devote to the patient, kindly instruction of the student. Compared with the hurried, infrequent rounds of our own busy attendants, it is something new and strange to watch a gray-haired surgeon, whose name is known throughout the world, surrounded by his little group of eager listeners, while he repeats and re-repeats to them the results of his own years of experience, teaching them that no case is too insignificant for their careful observation. It may be that this method of instruction is calculated to make the pupil one-sided in his views, but it has at least the merit of making his knowledge exact. This course may be impossible in the hurry and rush which characterize our educational as well as business plans, but it is something to be aimed at, if not attained. The dresser is a peculiarity of English hospitals as compared with our own. Each student must have served in that capacity for six months before being allowed to apply for his final examination. The result is that, instead of the practical training enjoyed by only a fortunate few among our students, every English medical man must have had such advantages before he is permitted to practice. Your readers may remember that there appeared in an American journal a few years ago a letter from an English physician who stated that an American student could "graduate without ever having seen a case." This letter provoked a vigorous reply from the late Dr. Gross, in which, though in his usual earnest style the venerated writer asserted his belief in the thoroughness of his

own pupils' training, it was still painfully evident that he had not succeeded in refuting the original charge. This is still more apparent when we remember that the British licensing bodies require a certificate of attendance on *twenty* cases of midwifery. Only *two* are required at Harvard; and how many men graduate every year in New York without having seen a single case! Yet we have just as large a *clientèle* as the London schools, compared with the number of students. That our students can go into practice without the least experience in handling cases is too well known to need contradiction. Not but that they have fine opportunities; the point is, they are not *obliged* to improve them.

And this leads to another thought. How do our institutions compare with those in England, and what is the essential difference in the training of their respective students? In the writer's opinion, the difference is that between *diffuse* and *exact* knowledge. The English student is constantly called upon to give a reason for the hope that is within him; the everlasting "Why?" stares him in the face at every turn; he is obliged to pick his way through details which the American takes at a flying leap. Doubtless the native ingenuity of the latter gets him out of many a scrape where his English friend would flounder helplessly through want of a proper precedent, yet, after all, since the object of a professional education, as of any other, is simply to teach a man to think for himself, it is just as well that he should do his thinking in a systematic way.

It is this lack of *exact* knowledge which makes an English examination so difficult for an American, even after his eighteen months of hospital experience. He has learned all of the minutie of hospital work, has had far more responsibility than any English house-surgeon can boast of, and yet before the merciless (though simple) questions of a strange examiner, who does not regard him as a prodigy at all, he feels that he has never learned to ask himself why he has done thus and so. Now that it is becoming much the fashion for our countrymen to apply for foreign degrees, it is well for them to bear in mind that neither success at home nor confidence in their own ability can take the place of the thorough, precise knowledge which must be acquired before they can expect to compete with their English rivals. And this can only be properly acquired by actual residence in London and daily routine work in the hospitals and museums. This is a prospect by no means attractive, and, from a financial point of view, it does not pay; yet the writer feels that the training for an English examination (which is really identical in its nature with that for a university boat-race) is not without its benefits. As the latter produces men of stalwart frame, so the former has brought forth a body of educated medical men of whom any country may feel proud. Doubtless many men "over-train" in both contests, but, through the survival of the fittest, those who are good are very good indeed.

To conclude without a word of apology would be to expose myself to the charge of disloyalty toward our own institutions. Far be it from any American to be ashamed of his Alma Mater. She has nourished noble sons, and will ever do so. Why should we shrink from comparisons? If they expose our weaknesses, they at least show our strong points. When we think that it has not been in the foremost medical colleges that our most honored representatives began their careers, we are tempted sometimes to think that, after all, preliminary training is a small affair beside native force of intellect. But, so long as the average man can never be a Sims or a Gross, it is desirable that he should be an educated gentleman, and this is the noble end toward which our professional schools are certainly tending—what more honorable cause of rivalry between us and the mother country?

FRANK P. FOSTER, M. D.

NEW YORK, SATURDAY, JUNE 28, 1884.

CHRONIC ALCOHOL POISONING.

First Article.

M. DUJARDIN-BEAUMETZ has just published an account of some extensive experiments which he has recently performed in the *abattoirs* of Grenelle, Paris, on chronic alcoholic poisoning. The subjects of his experiments were hogs, about twenty of these animals being subjected, and for a period of nearly three years, to daily dosing with small quantities of alcohol, the spirit being mixed with their food. As the results are of the greatest scientific interest, we will give a summary of M. Dujardin-Beaumetz's reports.

In enumerating the general effects of alcoholic poisoning upon the animals on which he experimented, he takes up in their order the different physiological systems, and describes the symptoms observed during life, and the post-mortem lesions. Whenever the daily dose of alcohol did not exceed one gramme for each kilogramme of the animal's weight, the digestive system bore it with very little inconvenience. An idea may be formed of the quantity here indicated by supposing the case of a man weighing one hundred and twenty pounds; such a man, if the human constitution is affected by alcoholic stimulants like the porcine, might ingest with reasonable impunity about two ounces of alcohol a day, say, in the form of a gill of good whisky. When the dose mentioned was exceeded, the experimenters constantly observed, in the course of a few days, the following symptoms: Loss of appetite, more or less marked; vomiting of bile and gairy mucus; and diarrhoea, more or less abundant, the stools sometimes containing a mixture of mucous and sanguinolent matters. These phenomena on the part of the alimentary canal sometimes took on so acute a character that it was found necessary to suspend the administration of the alcohol, and put the animal on a milk diet. In several post-mortem examinations which were made by M. Dujardin-Beaumetz and his assistant, they discovered an abnormal redness of the mucous membrane of the stomach. These stomachs were carefully compared with those of animals that had not been dosed with alcohol. The injection was limited to the mucous membrane, and there was no thickening of the walls of the stomach. In a few cases the mucous membrane of the intestine was congested; in certain points it presented a violaceous, ecchymotic tint, comparable to that which has been observed in rapid poisoning with alcohol.

As regards the hepatic system, several of the hogs presented, during life, a yellowish discoloration of the conjunctiva, and the urine was tinged with bile. Post mortem, the liver was found congested, and, in certain cases, its parenchyma was friable, but there was neither interstitial hepatitis nor ascites.

This is remarkable, considering that these swine had been subjected for more than two years to the alcoholic regimen. It is, however, a noteworthy fact that the connective-tissue framework of the hog's liver is more dense and resisting than that of man.

"Our animals," says M. Dujardin-Beaumetz, speaking of the urinary system, "never had hæmaturia; their urine, the density of which was always normal, and in which we never found albumin, was colored only by bile. The post-mortem examinations which were made revealed fatty degeneration of the kidney. M. Cornil, in his histological examinations, was at first struck with this steatosis. But this fatty change is almost constant in hogs. Therefore we think that it can not be attributed to the alcoholic regimen imposed on our subjects. In one of them there was pyelitis. Was this pyelitis produced by alcohol? We can not affirm this, although it seems probable."

Speaking of the respiratory system, the author continues: "Almost all our hogs had a cough, and some of them never ceased to cough. At the post-mortem examinations of the latter we noted marked pulmonary congestion, which, in a few instances, had given rise to hæmorrhages. This alteration seems to us to have had a double origin. It may be attributed in part to elimination of alcohol by the respiratory passages, and in part to atmospheric influences (the weather a part of the time being very severe). It is worth noting also that during the period of alcoholic hebétude which followed the ingestion of the spirit, and which lasted several hours, the animals remained immovable in their pens, and readily became chilled. This condition undoubtedly favored the development of broncho-pulmonary catarrh."

No circulatory disturbances were noted in these animals, although the least exertion induced a state of breathlessness. The heart, in every instance, appeared fatty, but hogs, according to M. Dujardin-Beaumetz, are exceedingly liable to fatty heart under any kind of alimentation. The valves were healthy. In several cases, however, atheromatous patches were noticed at the root of the aorta; these were limited to the first portion of that vessel. The experimenters were disposed to attribute these atheromatous patches to alcoholic poisoning, especially as they failed to find similar aortic mischief in other hogs that had arrived at the same age and had not been subjected to the same systematic dosing.

ENGLISH CRITICISM OF AMERICAN SANITATION.

PROPER criticism is one of the most valuable services that man can render to his fellow-man. There is some difference of opinion, however, as to what constitutes propriety in criticism, and there seem to be persons who think it necessary, not only to overstate the case, but also to humiliate those against whom the case is to be made out. A recent correspondent of the "Lancet" appears to be of this way of thinking, for he is at some pains to paint us blacker than we supposed ourselves to be, and that, too, in regard to two matters concerning which we have generally thought ourselves capable of standing a com-

parison with other communities—the efficiency of our medical practice and our common honesty as a people. “I say it adversely,” he observes, “but emphatically, after several years of close observation in the United States, that the rate of mortality generally, as well as in the city [New York], would be very materially lowered if the standard of medical education were adequately raised.” It is indeed wholesome for us to be made the subjects of such a statement as this, especially since it is evident that the writer aims not so much to deliver himself of the truism which it constitutes as a general proposition as to call attention to the exceptional ignorance of the medical practitioners of this country.

The other count of the indictment has reference to the United States census in so far as it relates to the city of New York, the resident population of which town, the writer of the communication is “well assured,” is estimated too high rather than too low if set down at one million. In support of this statement, he alleges the frequent double registration of individuals, and adduces the instance of himself and his family, who were “taken twice at the last census.” How humiliating this is! It is indignity enough that a Briton should be included once in the list of inhabitants of the United States, but twice—we can not express our chagrin that so base a deed should have been perpetrated. The point of this arraignment of the census is, of course, to make out that the death-rate of New York is even higher than the official figures indicate, that our real rate of mortality is 34·01, instead of the estimated rate of 25·81. He rules out the plea that there are many deaths in the public institutions of persons who arrive from foreign parts with a very poor prospect of life by the “child-like and bland” suggestion that, since they figure in the census, their deaths should also justly be reckoned in the bills of mortality.

Having made out this high death-rate, he imputes it to “bad drainage, bad water, bad air, bad food, imperfect sanitary measures, the herding together of many families in tenement-houses and rookeries as London can not equal for filth and rottenness of every kind, and last, but not least, to the inefficiency of medical help.” We beg leave to suggest that this list of ætiological factors is incomplete; indeed, the part of Hamlet is left out, namely, the universal enervation of the American people, as was illustrated about five years ago by another correspondent of the “Lancet,” who said in substance that no American ever ran when he could possibly walk, walked when he could possibly ride, stood when he could possibly sit, or sat when he could possibly lie down. It seems to us singular that, “after several years of close observation,” our friend has not felt impelled to include this physical degeneration in the indictment; but perhaps he thinks his criticism is best taken in divided doses.

The pangs of conscience aroused by the “Lancet’s” correspondent are somewhat tempered by what an English physician resident in New York has to say in the “British Medical Journal” for May 24th. This gentleman bewails the mismanagement of the English Transatlantic passenger steamship service as

regards its sanitary element, and pictures the horrors that may some time come upon us, in the shape of an imported pestilence, as the result of that mismanagement. While castigating his countrymen, he does not omit, however, to bestow some of his attention upon our methods of quarantine. But even he thinks, apparently, that his criticism needs to be administered heroically, for, after depicting the laxity of the Health Officer of the port of New York, he says: “Thus is quarantine administered in the United States.” Almost any palliation may cheerfully be allowed those who, being European by birth and education, find themselves condemned to a residence in the United States for a certain length of time; and how grateful we should feel when they mercifully give that palliation the form of criticism meant for our own profit and tending to our regeneration!

NEWS ITEMS, ETC.

INFECTIOUS DISEASES IN NEW YORK.—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending June 24, 1884:

DISEASES.	Week ending June 17.		Week ending June 24.	
	Cases.	Deaths.	Cases.	Deaths.
Typhus	4	0	6	2
Typhoid Fever	8	6	12	5
Scarlet Fever	65	12	54	16
Cerebro-spinal meningitis	4	4	6	5
Measles	92	14	181	33
Diphtheria	37	23	38	16

CHOLERA IN EUROPE.—A number of deaths from cholera have taken place at Toulon, on the Mediterranean coast of France, and a transport ship from China, suspected of having brought the disease to that port, has been ordered to sea. It is alleged that the first death from cholera at Toulon took place so long ago as the 4th inst., but that it was kept secret. A Cabinet council has been held at Madrid to take measures to prevent the entrance of the disease into Spain. The condition of Toulon is said to be one of extreme filthiness.

SMALL-POX FROM CHINA.—According to a newspaper dispatch, a Chinese woman landing from one of the Pacific Mail steamships last week succeeded in eluding the vigilance of the quarantine officers, although she had with her a small boy with the eruption of small-pox so pronounced on his face as to attract the attention of the customs officers. It is said that five hundred Chinese had already landed from the vessel when the discovery was made, but that the sanitary authorities at once proceeded to “corral” the six hundred that remained on board and to quarantine the ship.

M. PASTEUR’S EXPERIMENTS IN THE PREVENTIVE INOCULATION OF HYDROPHOBIA, according to “Lyon médical,” are to be prosecuted, at his request, under the observation of the following commission: M. Bédard, dean of the Paris faculty of medicine; M. Paul Bert, professor of physiology; M. Bouley, professor of comparative pathology at the Museum of Natural History; M. Villemin, of the military school of applied medicine and pharmacy; M. Vulpian, professor of comparative and experimental pathology in the Paris faculty; and M. Tisserand, director to the Minister of Agriculture. Perhaps a more satisfactory test will result from the fact, recorded by the “British Medical Journal,” that a railway employee, having been bitten by a dog that was undoubtedly rabid, has placed himself under M. Pasteur’s care.

THE GROSS PROFESSORSHIP OF PATHOLOGICAL ANATOMY.—At a recent meeting of the Philadelphia profession, as we learn from the "Medical News," resolutions were adopted calling upon members of the profession and others to contribute to the endowment fund for a memorial professorship to be called the S. D. Gross professorship of pathological anatomy. It is announced that contributions may be sent to Dr. R. J. Dunglison, lock-box 1,274, Philadelphia.

A CREMATORY FOR NEW YORK, it is reported, is likely to be built before long in East Williamsburgh, a company having bought land there for the purpose.

A BILL FOR A NEW UP-TOWN HOSPITAL is among those that have failed to receive the signature of Governor Cleveland, the reason given by the Governor being that the proposed hospital does not meet the views of the Commissioners of Public Charities and Correction.

THE UNITED STATES MEDICAL COLLEGE OF NEW YORK AND THE BUFFALO COLLEGE OF PHYSICIANS AND SURGEONS seem to have reached a crisis. The Court of Appeals has affirmed the judgment rendered by the Supreme Court about a year ago in the case of the first-mentioned concern, setting its charter aside, and the appeal which has now been passed upon was understood as a test case by the attorneys who acted in behalf of the Buffalo College.

THE NATIONAL BOARD OF HEALTH.—A dispatch to the "Evening Post" states that it has been discovered that the Sunday Civil Bill abolishes the board.

INCREASED ACCOMMODATIONS FOR THE INSANE OF NEW YORK are contemplated by the Commissioners of Public Charities and Correction, and the purchase of a tract of land on the line of the Long Island Railroad for the purpose is under consideration. The land in question is situated between Deer Park and Farmingdale.

VIVISECTION IN GREAT BRITAIN.—According to the London "Times," an analysis of a return of the experiments performed during the year 1883 under the Vivisection Act shows that, while forty-four persons in England and Scotland held licenses under the act, only thirty-two of them performed experiments, and that in Ireland, where eight licenses were held, only four persons performed experiments. The experiments of all kinds numbered 525 in England and Scotland, and 34 in Ireland. Two hundred were carried out under the restrictions of the license alone, 55 under special certificates dispensing with the use of anesthetics, and 122 under certificates dispensing with the obligation to kill the animals while yet anesthetized.

ARMY INTELLIGENCE.—*Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from June 15, 1884, to June 21, 1884:*

MAGRUDER, D. L., Lieutenant-Colonel and Surgeon. Granted leave of absence for one month. Par. 7, S. O. 143, A. G. O., June 20, 1884.

HAPPESETT, J. C. G., Major and Surgeon. Granted leave of absence for four months. Par. 5, S. O. 141, A. G. O., June 18, 1884.

Changes in the Department of Texas.

PORTER, J. Y., Captain and Assistant Surgeon. Ordered from Fort Ringgold, Texas, to Fort Brown, Texas, as post surgeon.

MADDOX, T. J. C., First Lieutenant and Assistant Surgeon. Ordered from Fort Clark, Texas, to Fort Ringgold, Texas, as post surgeon.

BLACK, C. S., First Lieutenant and Assistant Surgeon. Ordered from Fort Concho, Texas, to Fort Clark, Texas, as post surgeon. S. O. 73, Headquarters Department of Texas, June 9, 1884.

NAVAL INTELLIGENCE.—*Official List of Changes in the Medical Corps of the Navy during the Week ending June 21, 1884:*

KNIGHT, J. S., Surgeon. Ordered before Retiring Board.

HERNDON, C. G., Passed Assistant Surgeon. Detached from Albatross, and ordered to attend officers of Navy and Marine Corps in Washington.

FLINT, J. M., Surgeon. Detached from Smithsonian Institution, and ordered to Fish Commission steamer Albatross.

LEACH, P., A-sistant Surgeon. Ordered for examination preliminary to promotion.

GARDENER, J. E., Passed Assistant Surgeon. Detached from U. S. S. Lancaster, and ordered to U. S. S. Powhatan.

BOYD, J. C., Passed Assistant Surgeon. Detached from U. S. S. Lancaster, and ordered to U. S. S. Powhatan.

SOCIETY MEETINGS FOR THE COMING WEEK.—*Tuesday, July 1st:* Buffalo Medical and Surgical Association; Croton Medical and Surgical Union (Katonah, N. Y.); Elmira, N. Y., Academy of Medicine; Medical Society of the County of Broome, N. Y.; Medical Societies of the Counties of Hudson and Union, N. J.

Wednesday, July 2d: Medical Society of the County of Richmond, N. Y. (annual).

Thursday, July 5d: Society of Physicians of the Village of Canandaigua, N. Y.

Letters to the Editor.

THE PHILADELPHIA DEBATE ON THE TUBERCLE BACILLUS.

UNIVERSITY OF PENNSYLVANIA, PHILADELPHIA, June 20, 1884.

To the Editor of the New York Medical Journal:

SIR: May I ask you to insert in your columns these lines, in order to allow me to take exception to certain statements which my friend Dr. Shakespeare, of this city, made on the occasion of a discussion on tuberculosis before our County Medical Society some months ago, and which were printed in the last (June 14th) issue of your valuable journal?

In relation to the bulk of Dr. Shakespeare's statements, it is not necessary to say anything, as they are not pertinent to the subject at issue, and merely of local and biographical interest; moreover, they represent only personal views, more or less gallant in expression, and really concern no one, and hurt no one.

There is, however, in the report of Dr. Shakespeare's remarks (page 675 of your journal), a statement of importance, and of such character that I can not leave it unchallenged. It may be due to some mistake of the stenographer, perhaps. I am quoted by Dr. Shakespeare as having made the declaration that "Koch had so far modified his views that he now admitted that neither the form, size, and aspect of the tubercle bacillus, nor its want of individual motion, nor its peculiar behavior toward staining fluids, distinguished it from any other bacilli."

This would be, evidently, a misrepresentation of Koch's view upon this point, and I am not guilty of it. What I ever said or published on this particular point was this: "Dr. Koch kindly demonstrated to me a number of specimens of bacilli, and, in particular, the appearance of these bacteria exhibiting under low amplification the peculiar S-like figure in the growths in masses.

Koch seems now to lay more stress upon this low-power appearance and upon the pathogenetic properties of the *Bacillus tuberculosis* as a distinguishing feature from other bacilli than upon the color test. During the conversation, he admitted that some other bacilli may also yield the same micro-chemical reaction as the tubercle bacilli, but insisted that the latter bacilli can not be stained brown. The failure of the tubercle bacilli to take the brown stain, he said, was the reason that they can not be well photographed (blue- and red-stained objects not being suitable for photographing)." (See *Bacillus* chapter in my second communication on tuberculosis.)

It is also cruel of my friend Shakespeare to say, as he does, in another part of the same remarks, *that I have accused Koch of unscientific work!* Those who have honored me, on various occasions, with their attendance in scientific meetings, in the lecture-room, or daily in the laboratory, and those who have read my papers, can testify that I have ever done justice to the work of the discoverer of the tubercle bacillus, even if, so far, I have had no reason to agree to all his conclusions.

Yours respectfully, H. F. FORMAD.

SOME REMARKABLE OPIUM-EATERS.

JEFFERSON, WIS., June 3. 1884.

To the Editor of the New York Medical Journal:

SIR: Allow me to correct Dr. Livingston S. Hinkley's statement that the woman *habituée* he refers to, who took eighty-five grains of morphine daily, is the champion opium-eater. I have met with worse cases among my patients, and those I mention here *I myself saw take the amounts stated*. One, a farmer, of southern Illinois, took in my presence the entire contents of a drachm vial of morphine, which dose he repeated once or more daily. Another, a railway employee, took from two and a half to three such vials, averaging one hundred and fifty grains of morphine daily. I am now treating a physician who took forty-five grains *hypodermically pro die* when he came to me—equal to about one hundred grains *per os*.

Let me add my experience in such cases. The railway employee above mentioned was experimented upon to ascertain whether the drachm doses were completely absorbed, etc. I found that he could not tell the difference in doses of morphine, in solution, when administered by me, after passing ten or twelve grains in amount; indeed, twelve grains had the same effect on him that four times the amount had, showing that, beyond ten or twelve grains, the morphine taken has no effect, and probably passes off with the stools. This, of course, does not affect my *hypodermically* addicted colleague, who professes to have used from seventy to eighty grains daily subcutaneously at times. After the system has accustomed itself to a certain amount, which I maintain to be about ten grains *pro dosi*, almost any additional quantity may be given with impunity.

Respectfully, etc.,

DR. J. C. HOFFMAN.

THE COLLEGE OF MIDWIFERY.

NEW YORK, June 23, 1884.

To the Editor of the New York Medical Journal:

SIR: Please publish the following, which is a copy of a letter received by me from Dr. James O'Reilly.

Yours truly,
JOHN ALSDORF.

303 WEST FORTY-SECOND STREET, June 19, 1884.

JOHN ALSDORF, M. D.

DEAR DOCTOR: A circular letter, entitled "A Chapter from the History of the College of Midwifery," was mailed March 19th to the mem-

bers of the County Medical Society. In that letter charges were made by me derogatory to your character which have been since explained, and I now take pleasure in withdrawing the statements made and express my confidence in your personal integrity and honor.

Very truly yours,

[Signed] JAMES O'REILLY, M. D.

Proceedings of Societies.

AMERICAN NEUROLOGICAL ASSOCIATION.

Tenth Annual Meeting, held in New York, Wednesday, Thursday, and Friday, June 18, 19, and 20, 1884.

Wednesday's Proceedings.—(Concluded from p. 697.)

THE HAMMOND PRIZE.—The secretary read the report of the Committee on the Hammond Prize Essay. One essay, in German, of great worth, had been received, but it was not considered as fully covering the ground indicated by the conditions of the circular, and the prize had not been awarded. Some discussion followed, in which there seemed to be a feeling that the prize should have been awarded if an opinion could be formed from the committee's report.

MACROSCOPIC ENCEPHALIC NOMENCLATURE.—Dr. B. G. WILDER, of Ithaca, N. Y., read a paper on this subject. Like other studies of the subject by the same author, the general purpose of the paper was to facilitate true advancement and discrimination in our knowledge of the gross anatomy of the brain. It was desirable to reduce the difficulties from the ponderous terms now in use. The reader advocated the adoption of brief, monomial technical terms, mostly by subjecting those in common use to abbreviation, translation, and combination. He also spoke of the advantages of the more frequent and systematic use of the various methods of classifying the encephalic parts, and thus their names, in accordance with the segmentation of the organ, its construction of cavities and parietes, and the division of the latter into commissures, etc., and especially the recognition of certain parts as hypertrophied, atrophied, or marginal (tænia, fimbria, crista, etc.). The specific recommendations were: 1. The substitution of *mesen*, *proen*, etc., abridgments (not abbreviations), for *mesencephalon*, *prosencephalon*, and other segmental names. 2. The designation of the ventricles by the word *celia*, in composition with the segmental prefixes, which would require *mesocelia* (*mesocoele*), etc. In this connection attention was called to the substantial coincidence of the author's series of *celian* names (first published in March, 1881) with the names more recently proposed by Professor T. J. Parker.

The discussion on Dr. Wilder's paper was postponed until Thursday afternoon.

TONIC SPASM OF THE DIAPHRAGM.—Dr. A. D. ROCKWELL, of New York, then read a paper in which he related a case supposed to be of this nature.

Thursday's Proceedings.

The discussion of Dr. Wilder's paper on ENCEPHALIC NOMENCLATURE was taken up.

Dr. WILDER could remain but a few minutes, and said he would leave the following resolutions to be acted upon by the society:

Resolved, That, in the opinion of this Association, the advancement and dissemination of an accurate knowledge of the macroscopic anatomy of the brain will be facilitated by substituting for many of the polynomial terms, technical and vernacu-

lar, now in use, technical names which are brief and consist each of a single word.

Resolved, That we recognize the advantages of using such compound terms as atropia, diatela, mesocœlia, hemiseptum, præcommissura, medipendunculus, postcornu, and cognate words, proposed by Professor B. G. Wilder, and see no serious objection thereto.

Resolved, That there be appointed by the chair a Committee on Macroscopic Encephalic Nomenclature, with instructions to report at the next meeting a list of such terms as, in their judgment, may properly be recommended for use.

It was decided to act upon these resolutions on Friday.

CAN LOCOMOTOR ATAXIA BE CURED?—Dr. GREENE M. HAMMOND, of New York, read a paper on this subject, which will be published hereafter.

Dr. W. A. HAMMOND, of New York, opened the discussion, having but a few minutes to remain. He thought the suggestion by the author, that the condition was one of congestion rather than true sclerosis, was correct. He related a case in which there had been all the symptoms of locomotor ataxia, and the iodide of potassium and mercury failed to be of any benefit. There was a presumable syphilitic history. He then gave codeine to produce sleep, and nitrate of silver, but without hope of special benefit. Two weeks later the patient was cured. He thought there must have been congestion affecting the central part of the cord more than others, and probably extending to the side columns.

Dr. ROBERTS BARTHOW, of Philadelphia, agreed with the author of the paper that cases of locomotor ataxia could be cured, but what kind of cases? He had been severely criticised for having reported a case of locomotor ataxia as cured, but it was one due to mercurial poisoning, and the ataxic symptoms disappeared under iodide of potassium. Certain syphilitic cases could be cured. There ought to be a distinction made between those cases due to syphilitic gummatosa and others in which there was a history of syphilis, the symptoms, however, not being directly, but secondarily, due to this disease. He believed, moreover, that certain cases of commencing sclerosis might be arrested, but there was a difference between an arrest of sclerosis and a return of the cord to its normal state.

Dr. C. K. MILLS, of Philadelphia, had seen a great many cases of locomotor ataxia, and also some of pseudo-locomotor ataxia. He had never seen a case of the former kind cured, while he had seen a good many of the latter kind end in recovery. Distinct syphilitic ataxia might be cured, as suggested by Dr. Barthow, by antisyphilitic treatment. He believed that there was a form of meningo-myelitis—a low grade of inflammation involving the membranes and the extreme periphery of the cord—which might give rise to symptoms of typical advanced sclerosis of the posterior columns, and in these cases the patients sometimes got well. Again, he believed that sometimes cases of neuritis became cases of sclerosis. There were forms of general neuralgia which were sometimes mistaken for locomotor ataxia, and these cases were curable. It was well known, of course, that there was a form of hysterical locomotor ataxia, and sometimes a combination of exposure to syphilis on the part of the patient and a certain condition of lowered nerve tone, which gave rise to a disease which was supposed to be syphilitic, but which was hysterical in character; and this condition was cured in course of time. True typical hysterical locomotor ataxia was, of course, curable. In these cases there was not likely to be absence of the patellar reflexes. His own impression was that we could not say that there could be limited congestion of certain columnar or other regions of the cord. He thought it more probable that there was real inflammation giving rise to the ataxic symptoms.

Dr. BIRDSALL referred to some cases in which there was an apparent cure of locomotor ataxia, but some months afterward symptoms took place which showed that the disease was progressing.

MULTIPLE NEURITIS.—Dr. S. G. WEBBER, of Boston, read a paper in which he briefly reviewed the literature of the subject and narrated the histories of four cases in considerable detail, and briefly referred to eighteen cases which had come under observation comparatively recently in the Boston City Hospital. It was only within a few years that a general inflammation of the nerves had been recognized. Up to this time he had found recorded six cases with autopsies and twelve cases without. Speaking of the eighteen patients who had entered the hospital, fourteen only had come under his own observation. The youngest was nine years old. One was four years old, but there was doubt as to whether the condition was one of multiple neuritis or of infantile paralysis. The oldest patient was fifty-one years of age. More than half were between twenty and thirty years old. There was an interval of from one week to four months after the beginning of the symptoms before the patients entered the hospital. Their stay varied from two days to six months. Only a few of the patients were able after three or four months to go back to their occupations. In most of the cases no cause for the disease could be assigned. In five the patients attributed it to taking cold. Nine were females. There were three adults. Disturbance of sensation was one of the most constant and persistent symptoms. Tingling or a sleepy feeling might precede the severe pain, but within a comparatively short time the latter came on. It might be confined to one nerve district or exist in several. Sometimes the patient could mark the course of the nerve by the pain. The character of the pain was aching, boring, shooting, or burning, varying in different cases. With the pain there were great hyperæsthesia of the skin and tenderness of the muscles, pressure causing excessive pain. Pressure over the nerve trunks gave more acute pain than when applied to the muscles. When the hyperæsthesia subsided sufficiently there was found diminution of tactile and other sensations. The special senses had only rarely been affected. Exceptionally the pain and tenderness had been very slight or wanting. Motion was early disturbed. At first there was stiffness, due in part to pain; subsequently, paralysis more or less complete. The muscles were not affected equally, but the paralysis was distributed according to the nerves most affected. Within a comparatively short time the limbs became contracted, the contraction being sometimes extreme. The heels might be drawn up to the thighs, and the knees nearly against the chest. The electrical reaction of the nerves and muscles showed changes. The various tendon reflexes, both deep and superficial, were generally absent. The temperature and pulse were elevated in the earlier stages of the disease, and, in two fatal cases, throughout. The temperature usually dropped afterward to nearly or quite normal. The pulse rate continued rather high. In a few cases mild delirium was noticed, most marked at night. One or two women showed something of an hysterical disposition. In some of the patients there was general wasting of the tissues. In others there was oedema of the limbs and of the face. Excessive sweating was observed in some. One patient had an abscess in the parotid region during convalescence. In the fatal cases the respiratory muscles became paralyzed, the voice was changed, deglutition was affected, and the patient died perhaps from entrance of food into the air-passages. The symptoms having been pointed out, it would not be very difficult to make the diagnosis in marked cases. It might be differentiated from anterior polio-myelitis by the pain, the hyperæsthesia, the tenderness over the nerve trunks, the diminution of sensation, the high pulse rate, and the more

gradual onset. Progressive muscular atrophy did not cause the sensory disturbances, nor the electrical changes. In lead paralysis the sensory disturbances were not so marked. The disease might be mistaken for rheumatic fever, for in the case of three or four of the patients who came to the hospital there had been a diagnosis of rheumatism. Spinal meningitis might be recognized by the greater amount of pain in the back, which was increased by passive motion, etc. One case had been reported in which there had been a diagnosis of locomotor ataxia. Dr. Webber referred briefly to the fact that the disease had been regarded as of bacterial origin in Japan. He gave the results of the autopsy in one or two cases, referred to the fact that different opinions had been entertained with regard to whether the disease was of peripheral or central origin, and stated with regard to treatment that salicylic acid seemed to cut short the pain in some cases, that morphine was necessary to relieve it in many, that the application of a cloth soaked in a solution of carbolic acid was a comfort, and that blisters over the course of nerves were of benefit in relieving persistent hyperaesthesia. It was well to try to avoid contractions by gentle extension. Massage, extension, and electricity were to be used a long time in overcoming contraction and promoting a return of power.

CHLORIDE OF GOLD AND SODIUM IN SOME NERVOUS AFFECTIONS; A PRELIMINARY NOTE.—Dr. BARTHOLOW then read a paper in which he first referred to the use of gold as a medicinal agent by the ancients and by some physicians of more recent times. There were three headings under which it was convenient to group the therapeutic powers of gold: its so-called alterative action, its action upon the nervous system, and its action upon the genito-urinary system. He had always preferred the double chloride of gold and sodium since he had learned how little diffusible the chloride was. The double salt was readily diffusible. He had had no experience with the oxide of gold. The usual dose of the gold-and-sodium chloride was one twentieth of a grain. In this quantity, administered two or three times a day, it appeared to have, as a primary action, the power to promote destructive metamorphosis, to improve the condition of the blood, and to increase tissue strength. If its use was kept up for a time, the tissue changes became more rapid, and waste occurred in excess of repair. The tissues which yielded most readily were connective tissue and pathological formations. Hence the utility of the remedy in sclerosis, whether nervous, hepatic, or renal. Especially in posterior spinal sclerosis and chronic interstitial nephritis he found the salt very efficacious. He was far from believing, however, that lost parts could be restored. When used in locomotor ataxia early and persistently, it had seemed to him to arrest the disease in favorable cases. In three cases he thought that not only the disease had been arrested, but the patients had been improved. Thus far, no gastric or intestinal disturbance had followed the use of this remedy. Favorable results had attended its use in certain cases of kidney disease. There was a form of hypochondriasis coincident with changes in the cerebral vessels, and, it might be, depending upon those changes, in which the gold-and-sodium chloride was effective. In time the uneasiness in the head, the vertiginous and other abnormal sensations, subsided, and the mental depression cleared up. It seemed to him that the ancient opinion that gold was a cordial in cases of melancholia was also supported by modern experience. It was of use, too, in certain nervous conditions characterized by spasm. One physician had told him that he employed no other remedy in cases of pseudo-croup and laryngismus. In various cognate affections it would be found useful. The same power rendered gold of great value in certain urinary and genital affections. He had referred to chronic interstitial nephritis. He

could mention many cases of albuminuria in which the curative effects of this remedy had been conspicuous. He presented these notes in advance of a more elaborate treatment of the subject, to awaken more general interest in the use of this agent. Wider and more varied experience was necessary to fix its position.

Friday's Proceedings.

ENCEPHALIC NOMENCLATURE.—The society took up the consideration of the resolutions offered by Dr. Wilder the previous day. The first resolution, relating to the appointment of a committee, was adopted, and the others were referred to that committee. The president appointed as such committee Dr. Wilder, Dr. Spitzka, Dr. McBride, Dr. Gray, and Dr. Birdsall.

THE EFFECTS OF INJURIES OF THE SPINAL CORD UPON THE EXCRETION OF CARBONIC ANHYDRIDE.—Dr. ISAAC OTT, of Easton, Pa., read a paper on this subject. The effect of injuries of the spinal cord upon the excretion of carbonic acid had been, so far as he knew, little, if at all, noted. The action of complete division of the cord upon the pulmonary exhalation had been observed in the course of calorimetric experiments by others. That the gray matter and white matter of the cord had different functions was axiomatic, and it was an important question what relation they sustained to the excretion of carbonic acid. This subject also had relations to the pathology of the thermo-inhibitory fibers of the spinal cord. The experiments which he had made were upon rabbits. He described the apparatus used for this purpose, and said the animals were kept in a chamber of a temperature of 100° F. If the cord of a rabbit was cut at about the junction of the dorsal and lumbar regions, the temperature would fall, unless the animal were placed in a temperature which approached that of the bodily temperature, in which case it would rise. This rise of temperature was due to division of the cord, and not to external heat. Thus, if the uninjured animal was placed in the warm chamber for some hours, no rise of bodily temperature took place, but, when the cord was divided and the animal replaced in the warm chamber, the temperature rose. If the cord was completely exposed, but not cut, the temperature would rise only a few tenths of a degree. If on the following day the same cord was divided, the temperature, although it would fall at first, would rise again several degrees. It made no difference in the majority of cases whether the white or the gray matter was divided. No rise of temperature had been observed after an hour, except in two cases. In most cases it then fell below normal. Professor H. C. Wood had made six calorimetric experiments, during which the cord was completely divided. In his six cases the excretion of carbonic acid was increased except in two, and in one of these much blood was lost.

A CONTRIBUTION TO THE STUDY OF HYSTERIA AS BEARING ON THE QUESTION OF OÖPHORECTOMY.—Dr. G. L. WALTON, of Boston, read a paper with this title. The operation should be limited to cases in which the symptoms were secondary to pelvic disturbance (such as cellulitis and cystic degeneration of the ovaries), as distinguished from the far more numerous cases in which the local symptoms were secondary to constitutional disorder. We might have to include certain cases in which no organic disease was suspected, but should be extremely conservative in this respect. We were ignorant of the exact relation of hysteria to ovarian disease. The theory was suggested that the loss of function in the cortical cerebral cells in hemi-anesthesia, for example, was due to spasm of the cortical blood-vessels, analogous to that supposed to exist in some forms of migraine. In favor of this theory were mentioned the rapidity of onset and disappearance of symptoms, the regularity of the "transfer," and the fact that other vaso-motor irregularities were common in hysterical patients. As supporting the theory,

Dr. Walton mentioned a case, previously published by him, in which left-sided spastic migraine coexisted with right-sided hemianæsthesia, and with left-sided intermittent retinal ischæmia, the blood-vessels of the right eye remaining unaltered. If this theory was correct, the starting-point for the vascular spasm lay probably in irritation of the sympathetic nerves of the ovaries in the cases under consideration. Theory, however, was of minor importance as compared with the practical questions, Was hysteria ever secondary to pelvic disease? and Could it ever be relieved by removal of the ovaries? Both questions could be answered probably in the affirmative, in view of reported cases. As an illustrative case of the rôle played by hysteria as an additional indication for operation, the case was reported of a patient operated upon by another physician, in which hemianæsthesia and convulsive attacks, added to extreme debility and severe pain during and between the catamenial periods, furnished the ground for operating after failure of other treatment. The ovaries were removed without the tubes. Relief of all symptoms followed, including the hemianæsthesia and the hysterical convulsions, and the general condition of the patient was much improved. The improvement had been continuous up to the present time, over four months after the operation.

An interesting discussion followed, by Dr. E. C. SPITZKA, of New York, Dr. MILLS, Dr. J. J. PUTNAM, of Boston, Dr. ROCKWELL, Dr. M. P. JACOBI, of New York, and the author of the paper.

TYPICAL HYSTERICAL SYMPTOMS IN MEN DUE TO INJURY, AND THEIR MEDICO-LEGAL SIGNIFICANCE.—Dr. PUTNAM read a paper in which he said the important point was that, more commonly than had been thought, there were symptoms of typical hemianæsthesia following injuries of the kind referred to, such as the patient could not have imitated even though all the other symptoms of hysteria had been present and had disappeared. Three cases of this kind were referred to, all occurring in men, and the fact was commented upon as affording valuable evidence of disease in cases which might have been supposed to be cases of simulation. Similar cases had been reported by German observers.

SCLEROSIS OF THE GREATER PART OF THE MOTOR CORTICAL ZONE OF BOTH HEMISPHERES, WITH SECONDARY DEGENERATION OF THE PYRAMIDAL TRACTS.—Dr. SARAH J. McNUTT, of New York, presented specimens and read the history of a case. The patient, a girl, had never been well, had shown symptoms pertaining to the nervous system, and it was believed by the author that the lesions found their origin in injury during instrumental delivery.

OPHTHALMOPLÉGIA EXTERNA PROGRESSIVA.—Dr. BIRDSALL reported two cases of slowly progressive paresis of all the external muscles of both eyes, the levator palpebræ, the recti, and the oblique, producing partial ptosis and nearly complete immobility of the eyeballs, with complete preservation of the functions of the internal ocular muscles, the iris, and the ciliary muscles. The accommodation was normal, as well as the reaction of the iris to light and the accommodative movements. There was no perceptible lesion of the fundus. Vision was normal in one case, and defective from irregular astigmatism in the other. There was no evidence of disease in any other cranial nerve or in any other part of the body; no headache, and no suspicion of syphilis. Both patients were males, aged, respectively, seventeen and twenty-nine years. Slower improvement occurred in one case under large doses of iodide of potassium and faradization of the eyes than in the other. Both cases were still under treatment. Dr. Birdsall held that the trouble could not be due to intra-orbital disease, nor to an intra-cranial lesion involving primarily the trunks of the nerves implicated, on account of the escape of those branches of the third nerve

which supplied the iris and the ciliary muscle; that it must therefore, be an affection of the nuclei of origin of the sixth, fourth, and parts of the third nerves, which supplied the external ocular muscles, these parts representing an associated system concerned in the movements of the eyeballs and in lifting the upper lid, somewhat distinct from the iris and the ciliary muscle, which were more intimately connected with the functions of the optic nerve, and with the regulation of light, and probably proceeded, so far as the sphincter iridis and the ciliary muscle were concerned, from nuclei in close proximity to, but distinct from, the nucleus of origin of the remaining third-nerve fibers, which supplied the external ocular muscles. A gross lesion or a local softening, such as a neoplasm, a meningitis, or an arteritis, could hardly affect so widely separated nuclei as the third, fourth, and sixth, and not at the same time affect the ciliary and pupillary centers and other neural tracts; degeneration within this system of associated muscles, nerve tracts, and centers, similar to the degeneration of progressive muscular atrophy and of labio-glossopharyngeal paralysis, appeared to be the most consistent theory of the pathology of the cases. Hutchinson, in 1869, had advanced this view (based on an atrophy in which the lesion was found by Dr. Gowers) to account for this class of cases, which von Graefe first called attention to. In most of Mr. Hutchinson's cases, however, the iris and the ciliary muscle were affected, and either this condition or indications of disease in other parts of the nervous system were present in all of his seventeen cases. Reference was made to the allied cases by other authors, and to certain relations between tabes dorsalis and progressive muscular atrophy, and also to syphilitic ocular affections.

A STUDY OF THE ETIOLOGY OF TABES DORSALIS, WITH SPECIAL REFERENCE TO THE EFFICIENCY OF SYPHILIS.—Dr. E. C. SEGUIN, of New York, not able to be present, had requested Dr. Birdsall to present the statistics which he had prepared from notes in private practice. There were seventy-two cases. Of these, twenty-two, or 30 per cent., gave a history of chancre; of chancre and secondary symptoms there were sixteen, or 22 per cent. Those giving no history of chancre or secondary symptoms were fourteen, or 19 per cent. Those in which there was no mention with regard to syphilis there were twenty, or 28 per cent. Thus, there was 52 per cent. with a history of syphilis, and 48 per cent. in which syphilis was not mentioned.

Dr. BIRDSALL said that at the last meeting of the association he himself had given statistics of about forty-two cases, of which only 9 per cent. gave a syphilitic history.

Dr. DANA was quite sure that among syphilitic sailors not more than one in a thousand had tabes.

MY SOPHOBIA AND *Folie du doute*.—Dr. DANA then read a paper on this subject. Two cases, one of each affection, of a marked kind, were related. The questions were raised, whether mysophobia should be classed with *folie du doute*, what significance should be given to morbid fears, and where they should be placed. The condition of *folie du doute* was usually classed among the monomanias. In most cases the disease could not be considered an insanity unless this term was used in a very wide sense. Dr. Dana had at first been inclined to think that the two classes of cases, mysophobia and *folie du doute*, could not be related, but he had changed his mind. It now seemed they were both varieties of abortive monomania, so to speak—conditions showing a morbid state of the brain in one direction. As to the interpretation which should be put upon morbid fears, he thought they were all to be regarded as simply psychopathic symptoms which were sometimes found in insanity, hypochondriasis, etc.

Dr. SPITZKA had seen as many as eighteen cases within fourteen months, and he had been struck by the fact that heredity played a very small part in the etiology; masturbation, among men, was the great cause. The results of treatment, medicinal and moral, had been quite gratifying.

Dr. LEONARD WEBER, of New York, could not see why mysophobia should be raised to the dignity of a subdivision of *folie du doute*. As to the cause, there was usually a history of exhaustion from masturbation or sexual intercourse in the male, and uterine disease in the female. He regarded mysophobia as simply one of the symptoms of hypochondria in the male and of hysteria in the female.

Dr. DANA did not think that, if Dr. Weber should see a marked case of mysophobia, he would confound it with hypochondriasis or hysteria. He did not understand that any author made a separate disease of the affection, but that it was a name for a psychopathic symptom, indicating that the person had a particular form of monomania or insanity. He had seen very little benefit from other than moral treatment.

THE MODIFYING EFFECT OF ANÆSTHESIA ON THE GALVANIC REACTION OF THE SPECIAL SENSES.—Dr. MASSEY related a case of partial anæsthesia of the fifth nerve. The patient was healthy, aged forty-eight, and became blind in both eyes, in the one year sooner than in the other. There was no assignable cause. Over the left eye there was a partially anæsthetic spot. A needle might be thrust through the skin without pain, but it was felt. To the faradaic current sensation was normal, and to the galvanic current the local effect on the skin was normal, but the sensation of tingling and the perception of taste were two thirds lessened. Vertigo was readily produced with the poles placed anywhere but over the anæsthetic area. In this area thirty-five cells were required, while but twelve sufficed at the opposite side of the forehead. No vision could be induced. The treatment was by the interrupted current to the eye and the numb spot, and increasing doses of sulphate of strychnine. There was an apparent result of decided increase in sensation at the numb spot. With increasing sensation there was a decrease of the number of cells required to produce dizziness and taste. This was a corroboration of facts observed by Althaus.

Dr. ROCKWELL said it was an interesting fact that sometimes when taste and smell were lost the galvanic current would fail to give the slightest sensation of metallic taste, and it was only as the patient recovered this sensibility that perception of metallic taste returned.

CEREBRO-SPINAL SATURNISM.—Dr. G. W. JACOBY related a case of marked saturnine ataxia ending in recovery under the use of iodide of potassium. He had been able to find reference to only three such cases.

Dr. AMIDON thought there should be no more doubt about the possibility of lead producing ataxia than about arsenic and mercury.

Dr. BIRDSALL had observed marked tremor in lead poisoning, but never absolute paralysis.

Dr. DANA said that cases of lead poisoning were quite common, and it was quite certain few had observed such effects as those mentioned by Dr. Jacoby.

The association then adjourned, to meet at the call of the council in 1885.

MEDICAL SOCIETY OF THE COUNTY OF KINGS.

Meeting of May 20, 1884.

The President, Dr. JOHN A. MCCORMICK, in the chair.

THE TREATMENT OF EPILEPSY.—Dr. LONDON CARTER GRAY read a paper on this subject. [See p. 710.]

Dr. ROCHESTER thought the reader of the paper had covered

the ground so well that very little remained to be said. He coincided with him with regard to the variability in point of time between the paroxysms. He recalled the cases of two sisters, now under his observation. One was about thirty years of age, and the other eighteen. The elder had had attacks, ever since the menses first began, regularly every month, of *grand mal*. Lately—that is, within the last ten years—she had had *petit mal*. The speaker had never seen her with an attack of *petit mal*, but the family said that she had them as frequently as every hour; then she would not have them for several days. This case had first come under his observation four years ago. There were at that time symptoms of uterine difficulty. The uterus was replaced, supported by a pessary, and hot-water injections were advised, but no medication, except attention to the general health. The following year, instead of having attacks every month, and some months twice, she had three attacks in a year. The second year she had two attacks. From that time to the present none, and he had seen her two days before this meeting. He did not regard the patient as cured. He regarded the attacks as simply postponed. The younger sister had *grand mal*, and, having been placed on the bromide treatment, with proper attention to her general health and diet, within the course of six months had had no attacks whatever. The peculiarity of these attacks was, that they appeared at certain times in the day. This was always between the hours of six and seven in the morning or evening. He had heard that the patient had had an attack within a month, and that it came on between nine and ten o'clock in the evening. He believed that there was no routine treatment for epilepsy, and certainly no cure for it.

Dr. HARCOURT referred to a case which occurred in his practice about four months ago, which he adduced in illustration of some of Dr. Gray's remarks. He was called to see a gentleman of fifty-seven years who was suffering from an unusually severe attack of migraine, confined to the left side. The usual remedies were employed without avail. Nothing afforded any relief except doses of Magendie's solution, ranging from twelve to eighteen drops, administered hypodermically. The patient had to be kept under the influence of the drug for almost five days. On the fifth day the doctor was sent for in haste. When he saw the patient he asked him how he felt, but received no reply. He repeated the question, with the same result, and the patient's wife said he had not spoken to her for about an hour. He was then raised to a sitting posture in the bed, and, while the doctor was examining the pulse, was seized with a very severe epileptic convulsion. This was the first he had ever had. Rest and quietude were enjoined, and a mixture containing equal parts of bromide of potassium and bromide of sodium was ordered. The next day he was unconscious as well as aphasic. The unconsciousness lasted eight days; then improvement gradually took place, so that in about two weeks consciousness was completely restored. It was quite different with regard to his speech; the aphasia lasted fully three weeks. He had the same name for every one that spoke to him, and to questions, no matter how different, he always gave the same answer; in fact, his vocabulary consisted of about half a dozen words, or rather expressions. He was quite conscious of his mistakes about the names of objects, yet, when a slate and pencil were given him, he would write down the same unmeaning expressions as before. During the whole time there was no difficulty with the urinary or digestive organs, the appetite was very good, he was much inclined to sleep, and the temperature differed very little from the normal during the attack. There was no paralysis except the aphasia, nor any derangement of sensibility. There was no syphilitic history, nor was there any irritation of either the genital or the digestive organs

that could be discovered. His family history was good; he had suffered from occasional malarial attacks, and had some difficulty with the left side of the heart, which was the result, probably, of an attack of articular rheumatism which he had about twelve months ago. The left pupil was considerably dilated. The treatment included mild, nutritious food; tonics, such as quinine, strychnine, etc.; and, on account of the epileptic seizure, the bromides of potassium and sodium were freely administered, and subsequently alternated with phosphide of zinc in pills. It was almost two months after the attack before he was able to attend to any business. He had been perfectly well ever since.

NOTES ON HOSPITAL TREATMENT.—A paper with this title, by Dr. B. F. WESTBROOK and Dr. ISAAC H. PLATT, was read by Dr. PLATT. [See p. 714.]

Dr. WESTBROOK wished to call attention to one or two points which had only been alluded to in the paper, and which deserved some further mention. In the remarks of Dr. Berger before the *Société de chirurgie*, referred to in the paper, that gentleman had said that the contra-indications to Estlander's operation were tubercular disease and amyloid degeneration. In regard to the latter, Dr. Westbrook wished to call the attention of the Society to the fact that, in 1881, Dr. Kretzschmar and himself had reported the case of a young girl who had suffered from empyema, with extensive amyloid degeneration of the liver and kidneys. The disease had been in existence several months before she came under Dr. Kretzschmar's care. At that time there was a fistulous opening in the left second intercostal space, a little to the left of the sternum. From this point the pus had burrowed beneath the skin for two inches, and discharged through a second opening below. There were one or two scars lower down, in the axillary and dorsal regions indicating the sites of former openings. The side was much retracted, and stinking pus issued from the sinuses. The liver occupied almost the entire accessible portion of the abdomen, extending downward and to the left far beyond the umbilicus. There was polyuria, with very copious albuminuria. The patient was in a condition of great emaciation and etiolation. The two fistulous openings were united by laying open the tissue which separated them, and a free incision was made in the second intercostal space large enough to admit the finger readily. The cavity was then washed out daily with an antiseptic solution, introduced through a catheter; and the patient received large doses of dialyzed iron and other tonics. The cavity gradually closed, and, *pari passu*, the liver steadily diminished in size, until it finally retired beneath the costal cartilages, while the polyuria and albuminuria slowly diminished, until they finally disappeared. The girl was now a robust and healthy person. The case was of great interest surgically, as showing that, even after extensive amyloid change had occurred, the prognosis was not hopeless, provided the suppurating cavity could be successfully treated.

In regard to the operation of von Langenbeck, it was a particularly good one in cases where a large accumulation of pus presented, as, if successfully managed, it gave great control over the discharge of the matter. His method was to separate the periosteum from the rib, and then use the trephine carefully, so as to remove the button of bone without disturbing the inner periosteum. When this was accomplished, the inner periosteum and pleura would be seen to bulge, and, with the wound held nicely open so that everything was in view, these structures could be carefully punctured and the pus allowed to escape as slowly as desired. The advantage of this control over the discharge was great, on account of the danger of syncope from the rapid removal of a large effusion. In such cases the intrathoracic pressure was positive, the heart was compressed, and,

owing to the obstructed diastole, the venous blood accumulated in the large trunks. When the pressure was suddenly removed, the blood rushing into the right heart over-distended it and might paralyze it in diastole. He had himself assisted at an operation in which, owing to the rapid evacuation, there was almost fatal syncope, and it was only by the prompt use of stimulants hypodermically that the patient was rescued from immediate death. In many cases he thought it advisable to remove a quantity of the fluid by aspiration, a short time before the operation, as had been done in one of the cases reported.

Dr. P. H. KRETZSCHMAR desired to say a few words in connection with the observations in the paper on night-sweats in phthisis, not so much in discussion of what had been said as to give emphasis to other methods of treatment. He referred particularly to two different modes—namely, sponging the patient with vinegar and water in the evening, and the administration of cold sage-tea at bedtime. The method advocated by Dr. Westbrook and Dr. Platt might be a good one, and in a hospital was undoubtedly an eminently successful one, but it could not be so well prescribed in private practice. Referring to the method recommended by Dr. J. H. Tyndale, of New York—namely, the daily subcutaneous injection of carbolic acid—he could not say he approved of it. He had tried it in five instances, covering a period in one instance of forty-two days, without any advantage to the patients, and, if the experience gained in five cases was worth anything, he would not advocate the daily injections of carbolic acid as an improvement on the older methods of treating pulmonary phthisis. To be sure, it produced no abscesses, but, if this was its greatest merit, he preferred to practice other and more efficacious methods. Dr. Tyndale, he said, was very enthusiastic about the favorable results obtained by daily injections of one drachm or more of a two-per-cent. solution of pure carbolic acid, and had informed him not only that he had seen a number of cases in which the hectic fever and the night-sweats had disappeared, but that he expected to see the antiseptic treatment of phthisis accepted as the treatment of consumption before long.

Dr. ROCKWELL thought there was an error in the date of the first presentation to the profession of the method of inserting the end of a tube in some dis-infecting liquid. It would be found fully stated in the State society's "Transactions" for 1879 or 1880. He thought it just that the credit of the measure should be given to the one to whom it belonged—namely, an American surgeon.

Dr. WESTBROOK would like to state that the method of continuous irrigation, as it was called, by having a tube pass from the thorax into a vessel containing a disinfectant, or even water, dated back even farther than Dr. Rockwell had stated. He had run across it in looking over an article by Wintrich, in Billroth's "Handbuch der speciellen Pathologie und Therapie," published in 1857. He referred to this operation as having been employed in France and Germany.

Z. T. EMERY, M. D., *Secretary*.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

Meeting of May 28, 1884.

REPORT OF THE OBSTETRIC DEPARTMENT OF THE PHILADELPHIA HOSPITAL FOR THE QUARTER ENDING APRIL 30, 1884.—Dr. THEOPHILUS PARVIN read the following:

By the kindness of Dr. Bernardy, my associate in term of service at the Philadelphia Hospital, the entire charge of the obstetric department was given me, while he had that of diseases of women and children. It seemed to me that by this division of labor both the interests of patients and of medicine would be best subserved; and I desire publicly, as I have done

privately, to express my gratitude to Dr. Bernardy for his consent to this arrangement. Further, let me gratefully acknowledge the zealous and faithful work of the internes serving under me in the collection of statistics and making observations, without which the preparation of this paper would have been impossible. My debt to these gentlemen, Dr. Phillips, Dr. Parkhill, Dr. Randall, Dr. Lazarus, and Dr. Voorhees, is very great. Some of the statistics and observations, or their results, have been given elsewhere; others will be presented you now, and still others wait another opportunity.

And now, gentlemen of the Philadelphia County Medical Society, unexpectedly invited to read a paper before you, and thanking you for the honor, my endeavor will be to present facts rather than theories, results more than reasoning, hoping that possibly some of the facts and results may be of present interest and of future use, and knowing that the discussion they may evoke will have these characteristics.

During my term of service at the hospital seventy-two women were confined; this number, however, includes two cases of premature labor, and one of miscarriage at six months and a half; there was one case of twins. In sixty-nine cases the vertex presented; presentation of a foot, of the breech, and of the shoulder, each occurred once; the presentation in the case of miscarriage is not given. Forty of the seventy-two mothers were primiparæ. Of seventy-three children born, thirty-nine were females and thirty-four males—a preponderance of female births which is at least remarkable.* Fifty-one of the mothers were white, twenty-one black. The average weight of the white children was seven pounds and a little more than two ounces; that of the colored children, seven pounds thirteen ounces and a fifth; there was thus a difference of eleven ounces in favor of the latter. The heaviest child was a white one, its mother a primipara; its weight was nine pounds and twelve ounces. Comparing the difference between white male and female children, it was a little more than one pound,† while the corresponding difference in black children was only two ounces and one fifth. Of course, the number of cases observed is too small to allow a positive conclusion, but it suggests that the difference between the two sexes in the white and in the black races in regard to weight of the new-born is much more marked in the former than in the latter. If the results obtained in these limited observations should be confirmed by more extensive ones, we would have a race distinction which is in perfect correspondence with a known ethnological law.

* The general relation between female and male births is 100 to 106. Illegitimacy slightly lessens this proportion, that is, increases the number of females born; and this is a factor adding to the number of female births at the Philadelphia Hospital, for illegitimate births are there the more numerous, but still it is not sufficiently potent to entirely reverse the law. This abnormal disparity between male and female births is not a mere accident of the three months, for, taking all the births of 1882 and 1883 and adding those of the first quarter of 1884. I find the number is 371, and of these 173 were males and 198 females. It would be interesting to examine the hospital record for a long series of years and ascertain if this disparity is the same, and this it is my intention to do.

While referring to the normal relation between male and female births, and the effect of illegitimacy upon it, I may mention the curious contradictions of these laws given by the statistics of Roumania: These show that the proportion of female to male births is 100 to 116, and, further, this proportion is not changed by illegitimacy.

† The difference in the weights of white male and female children is greater than it should be from these facts: first, a larger number of female children; second, in two cases of premature labor and in that of twins the children were females, and, their weights being small, of course reduced the average.

As to the average weight of the new-born, I may repeat what has been published elsewhere. At my request Dr. Phillips found, from examination of the Philadelphia Hospital records of white children born there, that this weight was seven pounds four and eight tenths of an ounce. The number from which this result was obtained was one thousand—five hundred males and five hundred females. The average weight of the males was seven pounds and seven and nine tenths of an ounce, while that of the females was seven pounds one ounce and seven tenths.

The average duration of labor in the black women was very nearly fifteen hours, while in the white it was thirteen hours and twenty-five minutes—showing a difference in favor of the latter of more than an hour and a half; that is, labor is shorter in the white than in the black women. This result is an unexpected one; nevertheless, here again the number of cases is too small to justify a positive conclusion. The duration of labor in white primiparæ was fourteen hours nine minutes; in black, nearly eighteen hours; in white multiparæ, twelve hours forty-two minutes; in black, ten hours sixteen minutes. The duration of the third stage of labor was in the whites twenty-one minutes, and in the colored thirty-three minutes.

And here let me, for the time at least, lay aside these statistics to consider the conduct of the third stage of labor. The subject invites consideration in this paper by the following facts: One of the colored women failing to expel the placenta within an hour after the birth of her child, the gentleman having charge of the case introduced his hand into the uterus and removed the after-birth by piecemeal, or at least the greater portion of it. That patient had septicæmia, and infected each of her neighbors; the colored obstetric ward at this time was terribly crowded, the beds so close together that a patient could almost roll from her own bed into the next one.

Shortly after this I was called to a woman in one of the white obstetric wards, who had been delivered of her child three hours before, but the placenta was retained. The patient's pulse was good; there was no hæmorrhage, nothing but the simple fact of delay in the third stage of labor. A little friction of the uterus, and compression of its fundus through the abdominal wall, caused the expulsion of the placenta in a few minutes. There was no fragment of the after-birth or of the membranes retained; the genital organs of the patient were not touched either by the interne or by myself in this delivery; nevertheless she had septicæmia. Finally, a third patient had the placenta retained for nearly five hours, and then it was expelled. She had septicæmia. These three patients recovered.

In studying the phenomena of placental delivery we find there are three stages, viz.: First, the separation of the placenta from the uterus; second, its extrusion from the uterine cavity after its conversion into a foreign body by its detachment; and third, its expulsion from the vagina. Delay may occur in any one of these stages—that in the last, of course, being the most easily remedied. The separation of the placenta from the uterus is made by uterine retraction, and probably, instead of being marginal in some cases, central in others, is usually general.

A practical question is here presented: Is this separation facilitated by ligating the placental end of the cord; in other words, ought the obstetrician to use two ligatures, or one? The advocates of two ligatures claim that in this case the placenta, being larger, fuller, and firmer, can not so well follow the retraction of the uterus as it can if thin and flexible from the loss of blood, and therefore in the former case is more certainly and completely detached. This is doubted by some, denied by others; nevertheless it seems rational. But, admitting its truth, it is certain that if a single ligature be used the placenta is

smaller, and hence can pass through a smaller uterine orifice; this practice, no matter what its effect upon the first, facilitates the second stage of placental delivery.

After uterine retraction has separated the placenta, uterine contractions expel it into the vagina, while the abdominal muscles, aided, it may be, in some slight measure by the contractions of the vagina, cause its final expulsion.

In the spontaneous discharge of the placenta from the uterus, it does not seem yet settled whether the placenta usually presents the fetal surface or the margin at the os uteri. The doctrine of Matthews Duncan has probably for the last few years been most generally adopted by British and American obstetricians; my own belief is that it is correct—at least in some thirty cases of delivery, taking the method advised by Dr. Duncan to test the presentation, I found in the majority that the placenta descended through the os with its margin presenting. French obstetricians have not accepted Duncan's views; and indeed the recent observations of Pinard and others seem to prove that the placenta usually presents by its fetal surface.

Now, a practical lesson from this study of the mechanism of placental delivery is, that, adopting the view of Duncan, traction upon the cord—a traction which, of course, is never to be made when the placenta is still attached to the uterus—is mischievous, for it interferes with the normal presentation; but, if the normal presentation be that of the fetal surface, such traction facilitates the second stage of delivery.

The time required for the spontaneous delivery of the placenta, as observed by Kabierske in one hundred cases in the Strassburg Maternity, varied from thirty minutes to twelve hours, as is shown by the following table:

24 times.....	30 minutes.
20 times.....	1 hour.
25 times.....	2 hours.
11 times.....	3 hours.
9 times.....	4 hours.
5 times.....	5 hours.
8 times.....	6 hours.
2 times.....	8 hours.
1 time.....	12 hours.

Few practitioners are willing to trust nature this far, but guard against delay in the delivery of the placenta by following the uterus down with the hand upon the patient's abdomen, employing expression and the method of the Dublin school, as the fetus is expelled, thus keeping the hand upon the uterus at least as a sentinel to warn of uterine relaxation, and, better still, as a stimulus to and a re-enforcement of uterine retraction. A general observance of this practice reduces to a minimum cases of post-partum hemorrhage, of delay in the discharge of the placenta, and of hour-glass contraction.

And now, coming to the practical point of more direct interference with the third stage of labor, what circumstances demand it, and how is it to be made?

I believe the teaching of the Philadelphia school has been favorable to early interference—at least such delay as shown by the Strassburg statistics would not have been allowed by her great teachers. Dr. Hodge advised moderate traction upon the cord at the end of half an hour, or of an hour; and Dr. Meigs stated that he never waited for the spontaneous extrusion of the placenta more than an hour and a half, for he always supposed that, if it would not take place in one hour, there was little prospect for its taking place in twenty-four hours. Now, with all reverence for the names of these great men, and with, I trust, due personal humility, it seems to me their teaching was wrong. Even moderate traction upon the cord, if the placenta be attached, is liable to do harm, and traction is not necessary

to find out whether it is detached. The statistics quoted prove that one can not make a time-table for Nature in regard to placental delivery; she may effect that delivery long after Dr. Meigs's hour has passed.

As long as the placenta is wholly attached, hemorrhage is impossible; the placenta is still a living structure, and one with the uterus; to tear it loose, to directly detach it from the uterus, opens the way for perilous hemorrhage. Not only this, but such artificial detachment is usually incomplete, is liable to injure the uterine tissue, and the operator's hand may be the bearer of septic germs, or these may pass in with the air admitted during the manipulation, and find a congenial soil for their development in fragments of placenta, or blood-clots that are retained in the uterus. Therefore, unless hemorrhage demands immediate interference, the obstetrician refrains from passing his hand into the uterine cavity for the removal of an attached placenta; a completely adherent placenta is not so dangerous as the intra-uterine use of the hand for its detachment. I believe, then, that armed expectation is wise in the latter case, only endeavoring, by suitable compression of the uterus with the hand acting through the abdominal wall, to determine or assist that retraction of the organ which is nature's method of separating the placenta. After the detachment of the placenta—a fact which is best learned by feeling a part of the organ with the finger passed into the mouth of the womb—we may, by friction and compression of the uterus, if needed, evoke uterine contractions which will cause its expulsion. Those who believe that the placenta presents its fetal surface at the os uteri, urge the value of moderate and continuous traction upon the cord, thus assisting the molding of the mass to the orifice through which it is to come. This conservative view as to the management of so-called retained placenta has been strongly presented by Siredey in his recent work upon puerperal diseases. The common expression, retention of the placenta, means very different conditions, each requiring its appropriate treatment.

Passing now to another topic, the relation of acute infectious diseases to the pregnant, or to the puerperal state. The history of the three months furnishes two cases of measles in pregnancy, and one of scarlet fever in puerperality. A report of the latter will appear in the next number of the "American Journal of the Medical Sciences," and therefore is not presented here. In both the cases of measles the eruption did not appear until after labor, but in each the interval was so short that the disease was present in pregnancy. In one case the disease had no evident effect upon pregnancy, and the puerperal period was normal. But in the other I believe premature labor was caused by the disease, for, though no accurate or definite information could be had from the mother as to when the pregnancy began—she was half idiotic—the child was small, feeble, and imperfectly developed. Abortion or premature labor is the result in the majority of cases when measles occur in pregnancy. The second patient had septicaemia, but, even with this complication, and though quite ill, made a perfect recovery.

Puerperal temperature is a subject of importance to which brief reference will now be made. I have here a temperature chart made by Dr. Phillips and Dr. Randall, from the charts of twelve women in whom puerperal convalescence was undisturbed; the chart includes eight days of the puerperal period. The highest temperature was on the fifth day, and then it was only 98° 8' F.

Temperature record from two daily averages of twelve cases of normal recovery from labor. The first temperature is that of a woman delivered within the preceding twenty-four hours:

Morning,	98° 4'	98° 4'	98° 2'	98° 2'	98° 2'	98° 4'	98° 0'	98° 2'
Evening,	98° 8'	98° 8'	98° 8'	98° 4'	98° 9'	98° 8'	98° 4'	98° 4'

There were opportunities for observing the influence of apparently trifling causes in producing marked elevations of temperature. Thus one patient, whose condition was normal, insisted upon getting up the fifth day and dressing herself; she did so notwithstanding the remonstrance of the nurse, and her temperature rose to a little above 100°. Either from feeling badly, or possibly from the moral influence of the thermometer, she was willing to return to her bed. Another patient, doing well apparently, save that her temperature was 100°, got up the fourth day; her temperature rose to 103°; she returned to bed; her temperature in a few hours was only 100°, and in two days was normal. In another case an irritant cathartic, or that which proved to be such—the bitartrate of potassium—was given the fifth day, and for a short time the patient's temperature was nearly 105°, but the next day it was normal. On the other hand, the gravity of a case may be much greater than the temperature indicates. Thus in a patient with fatal septicæmia the temperature during the first five days only once rose as high as 101°, a part of the time was only 99°; on the sixth day rose to 102.2°, on the seventh fell to 101°, and then, on the morning of the eighth, was 103.2°; she died that day. In the abstract of a paper by Dr. Angus Macdonald ("British Medical Journal," May 10th) the statement is made that in some of the worst and most rapidly fatal cases of septicæmia the temperature never rose over 101°, if so high. The explanation given was that the vital centers were attacked with such a quantity of the poison that death occurred before the tissue-changes ending in heat took place. Dr. Macdonald further referred to the important difference in the course of temperature in lymphatic and in phlebotic septicæmia, there being in the former a single rigor with sudden and continuous high temperature, and in the latter a series of successive rigors followed by corresponding depressions. Siredey has previously remarked that a temperature chart of a patient having puerperal septicæmia will readily show whether the disease is the lymphatic or the phlebotic form. When Oslander, at the beginning of the present century, and others since him, described remittent puerperal fever, doubtless they had under observation cases of phlebotic septicæmia. I am sure these sudden and marked declines of temperature have led practitioners into false diagnoses, especially since attention was redirected by two distinguished American physicians to the occurrence of malarial fever in childbed; we would much rather believe a patient had this disorder than septicæmia, and such desire may assist the diagnostic error—an error I know that I have committed, and I have more than once witnessed its commission.*

(To be concluded.)

MICHIGAN STATE MEDICAL SOCIETY.

Nineteenth Annual Meeting, held at Grand Rapids, Wednesday and Thursday, June 11 and 12, 1884.

Wednesday's Proceedings.

ABOUT two hundred physicians being present, the meeting was called to order by the President, Dr. A. F. WHELAN, of Hillsdale. The Rev. B. F. SARGENT invoked the divine blessing, and the Hon. N. BELKNAP, Mayor of Grand Rapids, delivered an address of welcome.

*If any one should doubt the difficulty sometimes presented in diagnosing between septicæmia and malaria in childbed, he may be referred to a lecture delivered by Professor Luigi Mangiagalli upon malaria in its relation with the puerperal state ("Annali di Ostetricia, Ginecologia e Pediatria," 1883). In this lecture Mangiagalli remarks that, in the puerperium, the diagnosis between septicæmia and malarial infection is not always easy; that the difficulty may be most grave—almost insuperable.

COURTESIES AND ENTERTAINMENTS.—Mr. POWERS tendered his Opera House for the two days' session. The PENINSULAR CLUB offered the freedom of their club-house to the members of the Society during their sojourn in the city. Dr. and Mrs. CHARLES SHEPARD tendered the members of the Society a reception at their residence, No. 98 Ottawa Street. President HUGENBART offered to provide a special railway train for an excursion to Traverse City.

THE SECRETARY'S REPORT.—Dr. G. E. RANNEY, the secretary, read his report. There were 246 names on the roll of membership. Two honorary members had died during the past year, Dr. J. H. Jerome, of Saginaw, and Dr. William Brownell, of Utica. He had collected in dues and fees \$653, which he had expended or handed over to the treasurer, Dr. Smart. He now had on hand \$49.91.

THE REPORT ON SURGERY.—Dr. DONALD MACLEAN, chairman of the Committee on Surgery, gave a brief history of some interesting cases of surgery which he had had charge of during the past five months. He presented a number of his patients, and gave what might be called an excellent clinic.

EXPERT TESTIMONY.—Dr. S. P. DUFFIELD, of Dearbornville, read a very interesting paper in which he upheld the right of physicians to extra compensation for expert testimony in the courts. He cited a case in which he had charged \$250 for making an examination after poisoning by strychnine. The supervisors refused to pay his bill, but they did pay it rather than have the case go to the courts.

Dr. PRATT, of Kalamazoo, thought that medical men should confer with the legal profession to secure a different way of securing skilled testimony in the courts. We should seek to bring out scientific testimony, and not testimony leaning to one side. The courts should procure expert evidence, and this evidence should be scientific and nothing else.

THE DRY TREATMENT OF CHRONIC SUPPURATIVE INFLAMMATION OF THE MIDDLE EAR was the title of a paper by Dr. C. J. LUNDY, of Detroit.

Dr. McCALL, of Lapeer, discussed the subject at some length, and spoke highly of the use of boric acid.

THE USE OF TURPENTINE IN DIPHTHERIA.—Dr. GEORGE, of Ann Arbor, read a paper in which he related a favorable experience with this method of treatment. Out of a great number of cases, he had lost only one patient since he began to use turpentine.

EXPLORATION OF THE MALE URETHRA.—Dr. H. O. WALKER, of Detroit, presented a paper on this subject which was full of good suggestions. He also showed an instrument, a modification of Bigelow's evacuator, which was the best instrument he knew of for removing calculous fragments from the bladder.

PROSTATIC HYPERTROPHY.—Dr. A. B. PALMER, of Ann Arbor, read an interesting paper, giving histories of cases of hypertrophy of the prostate gland in old persons. He dilated the entire urinary passage by causing the patient to pass his urine, and, while a full stream was flowing, he seized the end of the penis with his thumb and finger, and, stopping the flow of urine, had the patient force the urine forward. In this way the entire passage was dilated.

THE DIAGNOSIS OF TUMORS.—Dr. T. A. MCGRAW, of Detroit, read a paper in which he advocated early and complete removal of all tumors.

Thursday's Proceedings.

PERINEPHRITIC ABSCESS.—Dr. G. K. JOHNSON, of Grand Rapids, read an interesting paper on perinephritic abscess, and related the histories of two cases which he had treated successfully.

THE TREATMENT OF ULCERS was the title of a paper read by Dr. DE CAMP, of Grand Rapids.

THE REPORT OF THE COMMITTEE ON ADMISSIONS was then made, showing about eighty applicants for membership. It was moved to amend the by-laws so that each applicant hereafter would be obliged to hand in the admission fee at the time of making his application, and providing that no member who had been dropped from the roll for non-payment of dues should be readmitted by petition until after nine years.

THE REPORT OF THE COMMITTEE ON NOMINATIONS was then presented, as follows: *Vice-Presidents*, Dr. J. PERKINS, of Owassos; Dr. J. M. COOK, of Muskegon; Dr. G. CHITTOCK, of Jackson; Dr. C. BRUMONE, of Detroit. *Secretary*, Dr. GEORGE E. RANNEY, of Lansing. *Treasurer*, Dr. A. R. SMART, of Hudson. *Judicial Committee*, Dr. OWEN, of Ypsilanti; Dr. TYLER, of Bay City; Dr. McCALL, of Lapeer. *Delegates to the American Medical Association*, Dr. BRODIE, of Detroit; Dr. BAKER, of Lansing; Dr. BENNETT, of Coldwater; Dr. BOOK, of Detroit; Dr. BRECKEY, of Ann Arbor; Dr. BRUMONE, of Detroit; Dr. CARSTEN, of Detroit; Dr. CLISBEE, of Coldwater; Dr. CONNOR, of Detroit; Dr. DUNSTER, of Ann Arbor; Dr. DUFFIELD, of Dearborn; Dr. FRENCH, of Battle Creek; Dr. HAGADORN, of Lansing; Dr. HITCHCOCK, of Kalamazoo; Dr. JOHNSON, of Grand Rapids; Dr. MACLEAN, of Detroit; Dr. COLE, of Lapeer; Dr. OAKLEY, of Ypsilanti; Dr. OWEN, of Ypsilanti; Dr. PALMER, of Ann Arbor; Dr. PRATT, of Kalamazoo; Dr. RANNEY, of Lansing; Dr. SIGNEY, of Pinkney; Dr. SHANK, of Lansing; Dr. SNOW, of Dearborn; Dr. SOUTHWORTH, of Monroe; Dr. TUPPER, of Bay City; Dr. TYLER, of Bay City; Dr. WADE, of Holly; Dr. WHELAN, of Hillsdale; Dr. SHEPARD, of Grand Rapids. *Committee on Legislation*, Dr. PRATT, Dr. PIERMONTE, Dr. TYLER, Dr. KARSON, Dr. SMART; *Committee on Reorganization*, Dr. JOHNSON, Dr. AVERELL, Dr. McCALL, Dr. CARMON, Dr. BRECKEY.

Dr. DONALD MACLEAN, of the University of Michigan, was elected president for the coming year.

PLACENTA PREVIA.—Dr. E. P. CHRISTIAN, of Detroit, read a paper on this subject.

CASES IN GYNECOLOGY were reported by Dr. CHARLES SHEPARD, of Grand Rapids.

NASAL CATARRH.—Dr. A. W. NICHOLS, of Greenville, read a paper in which he recommended quite a number of remedies, and stated that a committee of the American Medical Association had nearly come to the conclusion that little good resulted from a change of climate, except in a few cases of a permanent residence in Colorado or Dakota.

Dr. HEMINWAY stated that patients in the early stages of nasal catarrh were often troubled with sweating feet, and that soaking the feet in warm water often cured the catarrh. He also spoke highly of the vapor of iodine.

A number of papers were read by title and referred to the publishing committee without discussion. Papers by Dr. WADE, Dr. WARD, Dr. SULLIVAN, Dr. McCALL, Dr. SMART, and Dr. SMITH were thus read and hastily passed over.

THE ANNUAL ADDRESS.—President WHELAN read his annual address, which dealt with the history of medicine from the earliest time to the present day. In his opinion medicine had done much to break up the clouds of ignorance which prevailed during the Dark Ages; this it had done by building up the minds of the people, and, despite the bitter opposition there had always been against it, medicine had triumphed over all obstacles.

Dr. EUGENE SMITH, of Detroit, read a paper on GRANULAR LIDS.

Dr. KIRKLAND read a paper on AURAL CATARRH, the point of which was that deafness often came on insidiously from this cause, and that the person was nearly or quite deaf before he knew it, for the reason that the deaf ear was generally the one with which the patient seemed to hear best.

REMARKS OF THE PRESIDENT-ELECT.—THE PRESIDENT-ELECT, Dr. MACLEAN, was then escorted to the platform and introduced to the Society. He said that he must certainly be of a very old nature if he did not show his feelings toward the Society for the kindness and honor bestowed upon him. He hardly hoped or expected to make so good or so efficient a president as his predecessor, but he enjoyed the work and would try to make the next meeting as large as this one, if not the largest ever held. He said he had been in quarrels, but they had been mistakes of the head rather than of the heart. His intentions always had been and always would be for the good of the Society.

Dr. WHELAN said the communication sent in by the Woman's Temperance Union was upon a scientific subject, and he hoped some of the members would present papers upon that subject. [The communication suggested the preparation of papers on the effects of tobacco and alcoholic drinks.]

The Society adjourned, to meet at Port Huron the second Wednesday in June, 1885.

Miscellany.

THE INTERNATIONAL MEDICAL CONGRESS OF 1884.—The Eighth International Medical Congress will be held in Copenhagen, beginning on Sunday, August 10th, and ending on Saturday, August 16th. The following information is condensed from the official "Rules and Programme":

Membership.—Any medical man qualified by law to practice in his own country may become an ordinary member by registering his name, paying the subscription (20 Danish crowns), and taking out the tickets of admission. The registration will be conducted at the University buildings on and after August 9th (from 9 A. M. to 5 P. M. on the 9th, from 9 to 11 A. M. on the 10th, and from 8 to 9 A. M. on the following days). The inscription may also be obtained in advance by sending to the secretary-general, Professor C. Lange, the amount of the subscription, together with a specification of the applicant's name, position, and residence. Each member is entitled to a copy of the volume of "Transactions" when it is published.

Hotel Accommodations.—A bureau will be established at the railway station, where information in regard to lodgings, etc., may be had by members on their arrival.

The Journey to Copenhagen.—We earnestly advise those of our readers who intend to make the trip to Europe for the special purpose of attending the congress to take the Thingvalla (Danish) Line of steamships direct from New York to Copenhagen. Everything conducive to passengers' comfort and safety is as well managed on this line as on the more pretentious lines running to England, France, and Germany, while the charges are decidedly lower than on the more frequented lines. The trip takes from twelve to fifteen days, and is exceedingly interesting and picturesque, and persons who have never been in Denmark may derive much useful information about the ways of the country from the officers and crew during the passage. The sailings of the ships of this line, between now and the time of the assembling of the congress, are announced as follows: The Geiser, July 6th; the Thingvalla, July 19th; and the Hekla, August 2d. For further information, application should be made to Mr. G. C. Maringer, 21 State Street, New York. Another eligible line for the purpose is that of the Hamburg-American Steamship Company, since Hamburg is the point at which the routes from England to Copenhagen meet. There are two routes from Hamburg to Copenhagen: One by way of Kiel-Korsör, taking thirteen hours, including six hours at sea; the other by way of Fredericia-Nyborg-Korsör, taking twenty-five hours, including two hours at sea. From London one may reach Hamburg by the boats of the General Steam Navigation Company in about thirty-six hours; by way of Queensborough and

Flushing; by way of Dover and Ostend; or by way of Dover and Calais.

The Work of the Congress, which will be exclusively scientific in character, will be done in general meetings, for the transaction of business and for addresses and communications of general interest, and in fourteen sections. The election of general officers, a president, three vice-presidents, and a certain number of honorary vice-presidents and secretaries, will be in order at the first general meeting. The general meetings will be held from 4 to 5.30 P. M., but some extraordinary general meetings will be held in the evening, for addresses of a popular character. The addresses will be given only by those who have been invited to address the congress by the organizing committee. The official languages are French, German, and English, but brief remarks in discussions may be made in other languages, provided some member is willing to interpret for the speaker. The MSS. of addresses and papers are to be handed to the secretaries before the close of the congress, and those who take part in the discussions are requested to write out the substance of their remarks before the end of the day. As a rule, the reading of introductory addresses will be limited to twenty minutes, and in the discussions no speaker can be allowed more than ten minutes. Medical students, as well as ladies and gentlemen who are not members of the medical profession, but may be interested in the proceedings of any particular meeting, may be invited or allowed by the officers to be present at such meeting.

The Addresses are announced as follows: On Metaplasia, by Professor Virchow, of Berlin; On Morbific Micro-organisms and Vaccinal Matters, by Professor Pasteur, of Paris; International Collective Investigation of Disease, by Sir William Gull, of London; The Natural Production of Malaria and the Means of making Malarial Countries more wholesome, by Professor Crudeli, of Rome; The Neoplastic Diathesis, by Professor Verneuil, of Paris; On Investigations of Food Rations for Men in Health and Disease, especially in Hospitals, Infirmarys, and Prisons of different Countries, by Professor Panum, of Copenhagen.

The Sections will meet twice daily, from 10 A. M. to 12 M., and from 1 to 3 P. M. If the same or similar subjects are contained in the programmes of different sections, the sections may agree to discuss such subjects in common.

The Section in Anatomy.—Prepared Communications: The Cell-Nucleus and Cell-Division, by Professor Flemming, of Kiel; The Histology of the Striped Muscles, by Professor v. Ebner, of Gratz; The Origin of the Red Corpuscles of the Blood, by Professor Bizzozero, of Turin; The State of Glandular Cells during their Activity, by Professor Ranvier, of Paris; The Anatomy of the Labyrinth of the Ear, by Professor Retzius, of Stockholm; The Terminations of the Sensitive Cutaneous Nerves, by Professor Merkel, of Königsberg; The Mechanism of the Respiratory Movements, by Professor v. Meyer, of Zürich; The Rotatory Movements of the Forearm, by Professor Heiberg, of Christiania, and Professor Morris, of London; The Developments of the Form and the different Parts of the Heart, by Professor His, of Leipzig; The Development of the Branchial Fissures and Arches, by Professor Cadiat, of Paris. *Announced Communications:* On some embryological subject, by Dr. Allara, of Moscazzano; on the human venous system, by Professor Braune, of Leipzig; on several embryological subjects, by Professor Cadiat, of Paris; On the Functions of the Sympathetic Nerves, as deduced from the Anatomy of their Radicles, by Dr. Hoggan, of London; various communications, by Professor v. Kölliker, of Würzburg; The Variations and Development of the Lacrymal Bone, and its Relations to the Soft Parts of the Orbit, by Professor Macalister, of Cambridge; The Mechanism of the Foot, by Professor v. Meyer, of Zürich; The Nature of Certain Ligaments, by Mr. Sutton, of London; On the Remains of the Wolffian Bodies in Female Mammals, and on the Development of the Epithelium of the Esophagus in the Human Embryo, by Professor Tournoux, of Lille.

The Section in Physiology.—The following contributions have been promised: On Mucous Matters and their Relations to Albuminous Matters, by Dr. Hammarstedt, of Upsala; On the Part played by the "Fugitive Corpuscles of the Blood" in the Formation of Fibrin and in Coagulation, and on the Relation which the "Hæmatoblasts" of Hayem and the "Piastrine" of Bizzozero hold to the "Fugitive Discs of the Blood," by Professor Norris, of Birmingham, and Professor Hayem, of Paris;

On the Coagulation of Fibrin, by Professor Dogiel, of Kasan; On the Coagulation of the Blood, by Dr. Woodbridge, of Cambridge; The Relations between the Number of Red Corpuscles of the Blood and the Quantity of Hæmoglobin and of Dry Corpuscles of the Blood, by Professor Worm-Müller, of Christiania; Demonstrations on the Blood, by Professor Malassez, of Paris; Recent Investigations on Hæmoglobin and Methæmoglobin, by Dr. Otto, of Christiania; Absorptiometric Researches on the Dissociation of Oxhæmoglobin, by Dr. C. Bohr, of Copenhagen; On the Gases of the Secretions, especially of the Bile, by Professor Charles, of Cork; Demonstrations on the Structure and Changes of Muscular Fiber and Protoplasm with regard to their Relation to the Physiological Functions, by Professor Engelmann, of Utrecht, Professor Ranvier, of Paris, Professor Merkel, of Königsberg, and Professor Retzius, of Stockholm; The Changes of Glandular Cells during their Activity, and the Relation of those Changes to the Question of Trophic Nerves, by Professor Heidenhain, of Breslau, and Dr. Langley, of Cambridge; Inhibitory Action and the Inhibitory Nerves in general, by Dr. Gaskell, of Cambridge; The Causes and the Regulation of the Movements of the Heart in Animals during the Action of certain Poisons, by Professor Dogiel, of Kasan; The Center of Co-ordination for the Movements of Ventricles of the Heart, by Professor Kronecker, of Berlin; The Functions of the Cortex Cerebri, by Professor Munk, of Berlin; The Mechanism of the Circulation, by Professor Mosso, of Turin, Professor Marey, and Professor Franck, of Paris; The Experimental Pathology of the Circulation in Artificial Lesions of the Heart, by Professor Franck, of Paris; Instantaneous Photography in Physiological Investigations, by Professor Sanderson, of London, and Professor Mosso, of Turin; Instantaneous Photography in the Study of Voluntary Movements (at an evening session), by Professor Marey, of Paris; The Structure and the Function of the Labyrinth, by Professor Hensen, of Kiel, and Dr. Baginsky, of Berlin; The Specific Functions of the Cutaneous Nerves, by Dr. Blix, of Upsala; Ought Hereditary Transfer to be taken into Account in Lectures on Physiology? by Professor Hensen, of Kiel; Present Views concerning Deglutition, by Professor Kronecker, of Berlin; Automatic, Reflex, and Inhibitory Actions in Cardiac, by Dr. Openchowski, of Dorpat; Experimental Fistule of the Small Intestine, by Professor Panum, of Copenhagen.

The Section in General Pathology and Pathological Anatomy.—Prepared Communications: The Relation between Scrofulosis and Tuberculosis, by Professor Grancher, of Paris, and Professor Chauveau, of Lyons; Tuberculosis of Domestic Animals as a Source of Human Tuberculosis, by Professor Chauveau, of Lyons; Tuberculosis of the Cow's Udder, and Experiments in Inoculation and Feeding with Milk from Tuberculous Udders, by Professor Bang, of Copenhagen; Necrosis by Coagulation, by Professor Weigert, of Leipzig; The Morphological and Physiological Variability of Pathogenic Bacteria, by Dr. Koch, of Berlin; The Relations between Connective-Tissue, Parenchymatous, Blood-Vascular, and Cardiac Changes in Chronic Nephritis, by Professor Cornil, of Paris, and Sir W. Gull, of London; Acute Nephritis, especially the "Glomerulo-Nephritis," and Consecutive Cardiac Hypertrophy, by Dr. Friedländer, of Berlin; The Pathological Anatomy of Anæmia (author's name not mentioned); The Transformations of Cellular Elements in an Inflammatory Focus of Bacterial Nature, by Professor Cornil, of Paris. *Announced Communications:* On the Lesions Caused in Animals by the Jequirity Bacillus, by Professor Cornil, of Paris; On the Ixodes, a Human Parasite but little known, by Professor Roquemondane, of Limoges; The *Cysticercus cellulosus* in the Human Brain, and On the Relations of Anencephalia, Cyclopia, and Synotia with the Primordial Skull, by Professor Hannover, of Copenhagen; The Effects of the Infusion of Jequirity, by Dr. Salomonsen and Dr. Holmfeldt, of Copenhagen. *Demonstrations:* The Method of Projection for Demonstrations of Histological Preparations, and its Application in Lectures on Pathological Anatomy, by Professor Cornil, of Paris; The Pneumonia Micrococcus, by Dr. Friedländer, of Berlin; A Cavernous Formation between the Sclerotic and the Choroid of the Human Eye, hitherto unknown, by Professor Hannover, of Copenhagen; Mortal Emboli of the Heart and the Pulmonary Artery, by Professor Bang, of Copenhagen; The Culture of Bacteria in Capillary Tubes, by Dr. Salomonsen, of Copenhagen.

The Section in Medicine.—Prepared Communications: On a Uniform Nomenclature of Auscultatory Sounds in the Diagnosis of Diseases of the Chest, by Professor Flint, of New York; The Antipyretic Treatment of Acute Infectious Diseases, by Professor Liebermeister, of Tübingen, and Dr. Warfvinge, of Stockholm; The Antiseptic Treatment of Acute Infectious Diseases, by Professor Bouchard, of Paris; Clinical Observations on the Toxic Principles which are formed in Living Organisms, by Professor Lépine, of Lyons; Malarial Infection in Man, by Professor Crudeli, of Rome, and Professor Rosenstein, of Leyden; The Etiology, Diagnosis, Prognosis, and Treatment of Tuberculosis as Influenced by Recent Experiences in Pathological Anatomy and Experimental Pathology, by Professor Ewald, of Berlin; The Operative Opening of Pulmonary Cavities, by Dr. Bull, of Christiania; the Influence of Acute Infectious Diseases on the Kidneys, by Professor Stewart, of Edinburgh; Ulcer of the Stomach, by Professor Leube, of Erlangen; Peritonitis resulting from Diseases of the Vermiform Appendix, by Professor With, of Copenhagen; Is Acute Pneumonia an Infectious Disease? by Professor Jürgensen, of Tübingen; The Different Actions of japaconitine, pseudaconitine, and the French and the German aconitine, by Dr. Buntzen, of Copenhagen; The Different Forms of Diabetes Mellitus and their Clinical Characters, by Dr. Budde, of Copenhagen; The Value of Recent Researches on Blood-Corpuscles for the Pathology of Anæmic and Leucæmic Diseases, by Dr. Laache, of Christiania; The Treatment of Pleuritic Effusion, by Dr. Landouzy, of Paris. *Announced Communications:* On the Treatment of Diarrhœa and Dysentery in Persons who have returned from a Residence in a Hot Climate, by Dr. Ewart and Sir J. Fayer, of England; Subacute Pneumonia, by Dr. Grancher, of Paris; (Esophageal Auscultation, by Dr. Baréty, of Nice; On Atrophy Hemifaciæ, by Professor Lewin, of Berlin; On Baths and Douches of Condensed Air, by Dr. Dupont, of Paris; On Direct Transfusion of living Blood, and on Medicinal Hypodermic Injections, by Dr. Roussel, of Paris.

The Section in Surgery.—Prepared Communications: The Listerian Antiseptic Treatment in its Present Form, by Sir J. Lister, of London; The Iodoform Treatment, by Professor Mosetig-Moorhof, of Vienna; The Sublimate Treatment, by Dr. Schede, of Hamburg; The Treatment with Oxygenated Water, by Professor Bert, of Paris; Permanent Antiseptic Dressing, by Professor Esmarch, of Kiel; Anæsthetics in Surgery, by Professor Bert, of Paris; On Excision and Arthrotoomy in Tuberculous Joint Diseases, by Professor Ollier, of Lyons; Resection of the Stomach and the Intestinal Tube, by Professor Gussenbauer, of Prague; Nephrotomy (including Nephrolithotomy) and Nephrectomy, by Mr. Thornton, of London; Operations for Movable Kidney, by Dr. Hahn, of Berlin; Trephining in Localized Diseases of the Brain, by Dr. Lucas-Championnière, of Paris, Professor Ferrier, of London, and Professor Mollière, of Lyons; Osteotomy for Genu Valgum, by Professor Macewen, of Glasgow; Osteotomy for Club-foot (Cuneiform Osteotomy), by Professor Holmer, of Copenhagen; (Esophagotomy and Gastrostomy for Strictures of the (Esophagus, by Professor Studsgaard, of Copenhagen, Professor Verneuil, of Paris, and Professor Hjort, of Christiania; Colotomy and Extirpation of the Rectum for Malignant Disease, by Professor Bryant, of London, Professor Esmarch, of Kiel, and Professor Verneuil, of Paris; Cystotomy in the Diagnosis and Treatment of Tumors of the Bladder, by Professor Guyon, of Paris. *Announced Communications:* Operation for Congenital Dislocation of the Hip Joint, by Dr. Margary, of Turin; Articulation after Extirpation of the Larynx without Artificial Apparatus, and a Case of Cancer of the (Esophagus cured by Excision of that Organ, by Dr. Navaro, of Turin; Three Cases of Cholecystotomy, by Dr. Bœckel, of Strassburg; On Torsion of Great Arteries near their Bifurcation, by Dr. Wanscher, of Copenhagen; A New Method of Osteoclasis for Genu Valgum, by Dr. Robin, of Lyons; Osteotomy of the Hip, by Mr. Keetley, of London; On Massage, by Dr. Zabudowsky, of Berlin.

The Section in Obstetrics and Gynecology.—Prepared Communications: Antiseptics in Laparotomy, by Professor Mikulicz, of Cracow; On the Early Performance of Ovariectomy, by Mr. Thornton, of London; The Treatment of Myomata Uteri by Laparotomy, by Professor Kœberlé, of Strassburg; The Treatment of Uterine Tumors, by Mr. Tait, of Birmingham; Supravaginal Amputation of the Uterus by the Vagina as a Treatment for Tumors in the Posterior Uterine Wall, by Dr. Margary,

of Turin; The Destruction of Uterine Tumors by Electrolytic Puncture, by Professor Meunière, of Paris; Oöphorectomy as a Remedy for Nervous and Mental Sufferings, by Professor Hegar, of Freiburg; Vaginal Excision of the Cancerous Uterus, by Professor Schröder, of Berlin; The Operative Treatment of Extra-uterine Pregnancy, by Professor Litzmann, of Kiel; A Common International Nomenclature in Obstetrics, by Professor Simpson, of Edinburgh; The Significance of Albuminuria in Pregnant Women, by Professor Halbertsma, of Utrecht; The Cesarean Section and its Modifications, by Professor Müller, of Berne; A Comparison between Embryotomy, Cesarean Section, and Porro's Operation in Cases of Contracted Pelvis, by Professor Eustache, of Lille; On the Treatment of the Third Stage of Labor, by Professor Stadfeldt, of Copenhagen; Statistics of Puerperal Fever in Denmark, by Dr. Ingerslev, of Copenhagen. *Announced Communications:* On the Difficulties in Diagnosis caused by Hypertrophy of the Cervix Uteri, by Professor Horwitz, of Copenhagen; The Operative Treatment of Hematocele and Hematoma, by Professor Zweifel, of Erlangen; The Treatment of Sterility, by Dr. Madden, of Dublin; A New Operation for Ruptured Perineum, by Professor Kœberlé, of Strassburg; Partial Excision of the Peritonæum, by Dr. Sänger, of Leipsic; Uterine Adenolymphangitis, by Dr. Martineau, of Paris; Physiological and Pathological Remarks on Oriental Women, by Dr. Zambaco, of Constantinople; Congenital Lateropositions of the Uterus in their Relation to the Mechanism of Labor and to Peritumors, by Professor Lazarewitsch, of Kharkoff.

The Section in Ophthalmology.—Prepared Communications: On the Practical Value of Light-Sense Examination in Ophthalmology, by Dr. Samelsohn, of Cologne, Dr. Bull, of Christiania, and Dr. Bjerrum, of Copenhagen; The Color Sense, by Professor Holmgren, of Upsala; On the Examination of the Vision of Railway Functionaries, by Dr. Redard, of Paris; On the Methods of Testing the Color Sense of Seamen, by Dr. Brailey, of London; Latent Squint, especially Latent Divergent Squint, by Professor Graefe, of Halle, and Dr. Grut, of Copenhagen; On Some Forms of Keratitis, by Dr. Grut, of Copenhagen; The Determination of Refraction by Means of the Ophthalmoscope, by Professor Schmidt-Rimpler, of Marburg; On Blepharorrhœa Neonatorum, its Prevention and Treatment, by Dr. Christensen, of Copenhagen; On the Refraction of Infants, by Dr. Bjerrum, of Copenhagen. *Announced Communications:* The Artificial Ripening of Cataract, by Dr. Meyer, of Paris; Capsular Advancement of the Ocular Muscles, by Dr. de Wecker, of Paris; Diseases of the Conjunctiva and the Action of Jequirity, by Professor Sattler, of Erlangen; Trachoma and Amyloid Degeneration, by Professor Raehlmann, of Dorpat; Granulations and their Treatment, and On Extraction of Cataract without Excision of the Iris, by Dr. Galezowski, of Paris; Contributions to Ocular Therapeutics, by Dr. Seely, of Cincinnati; Inflammation of the Eye and its Surroundings from Astigmatism, by Dr. Martin, of Bordeaux; The Anatomy of the Ciliary Muscle, by Professor Sattler, of Erlangen; The Relations of Visual Disturbances and the Skin, by Dr. Mooren, of Düsseldorf; Opalescence of the Pupillary Area with Pellucidity of the Dioptric Media, by Mr. Watson, of London; The Results of Great Losses of Substance of the Cornea, and The Reaction on the Papilla of Lesions of the Anterior Parts of the Eye, by Dr. Gayet, of Lyons; The Mixture of Spectral Colors, by Dr. Dobrowolsky, of St. Petersburg; Obstruction of the Nasal Duct, and On Astigmatism, by Dr. Yuler, of London; The Color Sense, by Dr. de Grandmont, of Paris; Chronic Gastritis as a Cause of Certain Eye Diseases, by Dr. Christensen, of Copenhagen. *Demonstrations:* The ophthalmoscope for artists, by Dr. Adams, of London; hyperbolic glasses in keratoconus pellucidus, by Professor Raehlmann, of Dorpat; a self-registering perimetry, by Dr. McHardy, of London.

The Section in Pediatrics.—Prepared Communications: The Treatment of Chronic Diseases of Children at Seacoast Hospitals, by Dr. Scheepelen, of Refsans; The Normal Increase of Weight in Advanced Childhood, by Mr. Hansen and Dr. Wahl, of Denmark; The Prophylactic Treatment of Ophthalmoblenorrhœa Neonatorum, by Dr. Meyer, of Copenhagen; On the Choice of Antiseptics for the Treatment of Wounds in Children, by Dr. Rupprecht, of Dresden; The Value of the Pediatric Policlinic, etc., by Dr. Rauehuss, of St. Petersburg; Nephritis in Children, particularly in Babies, by Professor Kjellberg, of Stockholm; Meningitis Tuberculosa in the First Year of Life, by Dr.

Medin, of Stockholm; The so-called Acute Rickets, by Dr. Rehn, of Frankfurt on the Main, and Dr. Barlow, of London; Intestinal Invagination and its Comparative Frequency in Different Countries, by Professor Ribbing, of Lund, and Professor Hirschsprung, of Copenhagen; Croup from a Clinical Point of View, by Dr. Rauffuss, of St. Petersburg; The Pathology and Treatment of Infantile Cholera, by Dr. Baginsky, of Berlin. *Announced Communication:* On an easily Curable Form of Infantile Spinal Paralysis, by Professor d'Espine, of Geneva.

The Section in Dermatology and Syphilis:—Prepared Communications: On the Syphilitic Origin of Tabes Dorsalis, by Professor Fournier, of Paris; The Treatment of Syphilis with Mercurial Injections, by Dr. Liebreich, of Berlin, Professor Lewin, of Berlin, Professor Neumann, of Vienna, and Dr. Martineau, of Paris; The Tests of the Cure of Syphilis, by Professor Köbner, of Berlin; Excision of the Initial Sclerosis as an Abortive Treatment of Syphilis, by Professor Pick, of Prague, and Dr. Jullien, of Paris; The *Ætiology* and Pathology of Leprosy, by Dr. Hansen, of Bergen; A New System in the Pathology of the Skin, by Professor Schwimmer, of Buda-Pesth; The *Ætiology* of Lupus Vulgaris, by Professor Doutrelepoint, of Bonn, Professor Pick, of Prague, Dr. Leloir, of Paris, and Dr. Morris, of London; Lupus and Tuberculosis of the Skin, by Professor Kaposi, of Vienna; On the Time of the Cessation of the Contagiousness of Gonorrhea, by Dr. Bockhart, of Würzburg; On the Role of Micro-organisms in Skin Diseases formerly not considered Parasitic, by Dr. Unna, of Hamburg. *Announced Communications:* On Endoscopes, by Dr. Grünfeld, of Vienna; Syphilis in Animals, by Dr. Martineau, of Paris; On the Role of the Nervous System in Diseases of the Skin, by Professor Schwimmer, of Buda-Pesth; Late Hereditary Syphilis, and the Visceral Manifestations of Syphilis, by Dr. Barthelemy, of Paris; A Comparison of the Mercury with the Iodide-of-potassium Treatment of Secondary Syphilis, by Dr. Gouguenheim, of Paris.

The Section in Psychiatry and Nervous Diseases:—Prepared Communications: The Statistics of Mental Diseases and Psychiatric Institutions in the Scandinavian Countries, by Professor Steenberg, of Denmark; A Plan for Uniformity in the Reports of Lunatic Asylums in Various Countries, by Dr. v. Schwartz, of Buda-Pesth; The Value of Agricultural Colonies in the Treatment of Insanity, by Dr. Paetz, of Alt-Scherbitz; The Part played by Schools in the Production of Mental Diseases, and The Value of Exercises in the Treatment of Mental Diseases, by Professor Kjellberg, of Upsala; The Relation of Progressive General Paralysis to Syphilis, by Dr. Rohmell, of Denmark; Morphinism and its Treatment, by Professor Obersteiner, of Vienna; The so-called "Psychic Epileptic Equivalent," by Dr. Hallager, of Denmark; Secondary Degenerations in the Spinal Cord, by Professor Pitres, of Bordeaux, and Dr. Homen, of Helsingfors; Vaso-Motor and Tropic Neuroses, by Professor Eulenburg, of Berlin; The Histological Lesions in Amyotrophic Lateral Sclerosis, by Professor Charcot, of Paris, and Dr. Friedreich, of Copenhagen; The Curability of Tabes Dorsalis, by Professor Eulenburg, of Berlin. *Announced Communications:* Psychological Analysis as a Basis for Psychiatric Diagnosis, by Dr. Ramaer, of the Hague; The Dyscratic Origin of Physical and Nervous Disturbances, by Dr. Müller, of Blankenburg; Cretinism, by Dr. Allara, of Moscazzano; The Doctrines of Cerebral Localizations, by Dr. Shuttleworth, of Lancaster; Ataxic Disturbances of Speech without Cerebral Symptoms, by Dr. Chervin, of Paris; The Vascularization of the Medulla Oblongata, and Cerebral Irritation, Cerebral Compression, and Cerebral Paralysis, by Professor Adamkiewicz, of Vienna; Hysteria, Hypnotism, Ecstasy, etc., by Dr. Zambaco, of Constantinople.

The Section in Laryngology:—Prepared Communications: The Prognostic Significance of the Several Local Manifestations observed in Tuberculosis of the Larynx, by Dr. Solis-Cohen, of Philadelphia; Tuberculosis of the Larynx, by Dr. Gouguenheim, of Paris; Paralysis of the Larynx, by Dr. Semon, of London; The Treatment of Diseases of the Respiratory Passages by Inhalations, by Professor Schnitzler, of Vienna; The Pathology and Treatment of Chronic Naso-pharyngeal Catarrh, by Dr. Breggen, of Frankfurt, and Dr. Guye, of Amsterdam; The Treatment of Goitre, by Dr. Mackenzie, of London, and Professor Ribbing, of Lund; The Operative Removal of Foreign Bodies and Pseudoplasms from the Air-Passages, by Professor Voltolini, of Breslau, and Professor Lefferts, of New York; The Treatment of Diphtheria, by Dr.

Seifert, of Würzburg, and Dr. Nix, of Rude; The Treatment of Nasal Polypus, by Dr. Fauvel, of Paris; The Singing Voice, by Dr. Bosworth, of New York, and Dr. Browne, of London; Syphilitic Affections of the Larynx, by Professor Lewin, of Berlin. *Announced Communications:* A Manual for Laryngological Exercises, by Dr. Garrel, of Lyons; Photography of the Larynx, by Dr. French, of Brooklyn; The Accumulator and Galvanic Cauterization, by Dr. Bayer, of Brussels.

The Section in Otolology:—Prepared Communications: The Different Kinds of Subjective Sounds and their Treatment, by Dr. E. Woakes, of London, Dr. de Lacharrière, of Paris, and Professor Lucas, of Berlin; The Dissection of the Organ of Hearing, with Particular regard to its Pathological Changes, by Professor Voltolini, of Breslau, and Dr. Kirk-Duncanson, of Edinburgh; Nervous Ear Diseases, by Dr. Bull, of Christiania; Chronic Naso-pharyngeal Catarrh, by Dr. Breggen, of Frankfurt on the Main, and Dr. Guye, of Amsterdam; The Artificial Opening of the Mastoid Process, by Professor Schwartz, of Halle; The Diagnosis of Intra-cranial Complications in Suppurative Inflammation of the Middle Ear, by Dr. Robin, of Paris, and Dr. Green, of Boston; The Significance of Ear Diseases as to Ability for Military Service, by Dr. Bremer, of Copenhagen; The Treatment of Nasal Polypus, by Dr. Fauvel, of Paris; The Importance of Otolology for General Medical Education, by Professor Wreden, of St. Petersburg. *Announced Communications:* The Mechanical Treatment of Disturbances of the Sound-conducting Apparatus without the Air-douche, by Professor Lucas, of Berlin; Tenotomy of the Tensor Tympani in the Treatment of Deafness, and On Deaf-mutism considered from a Medical Point of View, by Dr. Giampietro, of Naples; The *Ætiology* of Deaf-mutism, and On the Instruction of Deaf-mutes, principally in Denmark, by Dr. Salomonsen, of Copenhagen.

The Section in State Medicine:—Prepared Communications: What can be done to check the Abuse of Morphine and other Preparations of Opium? by Professor Brouardel, of Paris; The Health of Danish and Swedish School Children, by Dr. Hertel, of Copenhagen, and Professor Key, of Stockholm; How can the Abuse of Alcoholic Liquors be best prevented? (author's name not given); How is Scoury to be prevented in Prisons and Workhouses? by Professor de Chaumont, of Netley; The Statistics of the Mortality from Phthisis in Danish Towns, by Dr. Lehmann, of Copenhagen; The Choice of Disinfectants (author's name not given); Legislation to prevent Accidents from Poisoning, by Dr. Berlin, of Stockholm; The Vacation-Stay of Poor Children in the Country, by Mr. Holbeck, of Copenhagen; The Prevention of Epidemics when a Single Case of an Infectious Disease has appeared, and the Diseases that ought to be subjected to such Measures, by Dr. Linroth, of Stockholm; Seacoast Hospitals for Scrofulous Children, by Dr. Engsted, of Copenhagen; The Application of Spectrum Analysis to Forensic Questions, especially in the Demonstration of Poisoning by Oxide of Carbon, by Professor Jäderholm, of Stockholm; The Hygiene of Churchyards, by Dr. Levison, of Copenhagen. *Announced Communications:* Vaccination, and On the Dissemination of Small-pox Virus through the Air, by Dr. Makuna, of England; The Prophylaxis of Yellow Fever, by Dr. Théréopolis, of Paris.

The Section in Military Medicine:—Prepared Communications: The Antiseptic Treatment of Wounds in Time of War, with particular regard to the Employment of Safe, Efficacious, and Simple Requisites of such Small Compass as to adapt them particularly to Military Surgery, by Professor Esmarch, of Kiel, Sir W. MacCormac, of London, Dr. Neudörfer, of Vienna, and Dr. Strube, of Berlin; Surgical Hemostasis in Times of Peace and War, by Dr. Neudörfer, of Vienna; Croupous Pneumonia among Soldiers, by Dr. Poulsen, of Copenhagen; Periostitis caused by Over-fatigue among Soldiers, by Dr. Laub, of Copenhagen; Pneumatometry as a Means of Testing the Health of Soldiers, by Dr. Dahlerup, of Nyborg; Allowances of Alcoholic Liquors for Soldiers and Sailors, by Dr. Schmulewitsch, of St. Petersburg. *Announced Communications:* The Hygienic Protection of an Active Army and of the Surrounding Country in the Rear, by Dr. Michaëlis, of Innsbruck; Sun-stroke, by Sir J. Fayer, of London; Typhoid Fever among European Soldiers and others in the Tropics, by Dr. Ewart, of Brighton; Medicomilitary Statistics as an Important and Unique Basis of International Statistics for European States, by Dr. Schmulewitsch, of St. Petersburg.
